In most cases, the magnitudes of the recoupled spin interactions depend on the orientation of the molecular reference frame with respect to the rotor. The only exceptions are when isotropic spin interactions such as the J -coupling or the isotropic chemical shift are selected, or in the special case of ‘zero-field in high-field’ experiments.^{28,29}

The orientation-dependence of the recoupled spin interactions creates both problems and opportunities. A powerful feature of the symmetry theory is that it allows the form of the orientation-dependence to be manipulated qualitatively by choosing certain combinations of symmetry numbers.

The recoupled spin Hamiltonian in equation (33) is proportional to the spatial tensor component in the rotor-fixed frame, defined through the transformation chain

$$[A_{lm}^\Lambda]^R = \sum_{m'', m'} [A_{lm''}^\Lambda]^P D_{m'' m'}^I(\Omega_{PM}^\Lambda) D_{m' m}^I(\Omega_{MR}) \quad (38)$$

Here $[A_{lm}^\Lambda]^P$ are components of the spatial tensor, expressed in its own principal axis frame. The expression in equation (38) depends on the three Euler angles $\Omega_{MR} = \{\alpha_{MR}, \beta_{MR}, \gamma_{MR}\}$ defining the orientation of the molecular reference frame with respect to the rotor frame. In general, the recoupled spin Hamiltonian is anisotropic, and depends upon all three orientational Euler angles.

2.13.1 γ -Encoding

Suppose that a particular set of quantum numbers $\{l, m, \lambda, \mu\}$ is symmetry-allowed in the average Hamiltonian. The spatial Wigner element has the following form:

$$D_{m'm}^l(\Omega_{MR}) = \exp\{-im'\alpha_{MR}\} d_{m'm}^l(\beta_{MR}) \exp\{-im\gamma_{MR}\} \quad (39)$$

This may be combined with equation (33) to show how a single recoupled term depends upon the Euler angle γ_{MR} , the time point t^0 at which the symmetry-based pulse sequence starts, and the rotor Euler angle α_{RL}^0 at the time point $t = 0$:

$$\begin{aligned} \overline{\mathcal{H}}_{lm\lambda\mu}^\Lambda(\gamma_{MR}, t^0, \alpha_{RL}^0) &= \overline{\mathcal{H}}_{lm\lambda\mu}^\Lambda(0, 0, 0) \\ &\times \exp\{-im(\gamma_{MR} + \alpha_{RL}^0 - \omega_r t^0)\} \quad (40) \end{aligned}$$

The three parameters γ_{MR} , t^0 and α_{RL}^0 may be included in a single complex phase factor.

It follows that only the *phase*, and not the *magnitude*, of the single term $\overline{\mathcal{H}}_{lm\lambda\mu}^\Lambda$ depends on the orientational Euler angle γ_{MR} . This property is termed γ -encoding of the recoupled term $\overline{\mathcal{H}}_{lm\lambda\mu}^\Lambda$.

In general, there are several symmetry-allowed terms $\overline{\mathcal{H}}_{lm\lambda\mu}^\Lambda$ with the same value of l , λ and μ but different values of m . Each of these terms contains the same spin operator $T_{\lambda\mu}^\Lambda$, but with a different spatial coefficient. These multiple coefficients interfere in a complicated way. As a result, the *complete* recoupled spin Hamiltonian is usually not γ -encoded.

It is possible to maintain γ -encoding of the entire recoupled Hamiltonian, by imposing a *one-to-one correspondence* between the symmetry-allowed spatial quantum numbers $\{l, m\}$ and the symmetry-allowed spin quantum numbers $\{\lambda, \mu\}$. This prevents the interference of terms with the same value of μ but different values of m .

For example, consider the symmetry $C6_2^1$. This leads to double-quantum recoupling of the DD terms, with suppression of all CSA terms to first order. The symmetry-allowed DD terms have the quantum numbers $\{2, -2, 2, 2\}$, $\{2, -1, 2, -2\}$, $\{2, 1, 2, 2\}$ and $\{2, 2, 2, -2\}$. The average Hamiltonian is *not* γ -encoded, since each spin term $\mu = 2$ is associated with two spatial components, $m = -2$ and $m = 1$.

If the symmetry number N is increased from 6 to 7, the symmetry $C7_2^1$ is generated, which only allows the DD terms $\{2, -1, 2, -2\}$ and $\{2, 1, 2, 2\}$. Since each spin component is now associated with only a single spatial component, the recoupled spin Hamiltonian is γ -encoded. Some of the success of the γ -encoding of the average Hamiltonian. For example, the theoretical maximum efficiency of double-quantum filtering experiments is usually increased by around 20% by using a γ -encoded pulse sequence.³⁶ In addition, γ -encoded pulse sequences enjoy much greater freedom in the relative timing of the pulse sequence and the sample rotation (see below).

The orientation-dependence of γ -encoded and non- γ -encoded sequences are contrasted in Figure 7. For γ -encoded sequences, the magnitude of the recoupled Hamiltonian is cylindrically symmetrical around the sample rotation axis.

2.13.2 Non- γ -Encoded Sequences

Although γ -encoding is generally a positive feature, it does have some disadvantages. As explained above, γ -encoding is

Figure 7 Polar plots showing the orientation-dependence of different dipolar recoupling sequences with respect to the magic-angle rotation axis (solid arrow). The direction of the external field is vertical. In each case, the magnitude of the recoupled Hamiltonian for a given orientation of the internuclear vector is proportional to the distance from the origin to the surface, in the direction of the vector. (a) γ -encoded recoupling of $m = \pm 1$ terms; (b) γ -encoded recoupling of $m = \pm 2$ terms; (c) non- γ -encoded recoupling

generally imposed by eliminating some components of the average Hamiltonian. This enhanced selectivity is generally accompanied by a reduction in the overall magnitude of the recoupled Hamiltonian. In some cases, for example in long-range distance measurements, this is a disadvantage, since the recoupled interactions compete with relaxation and other loss processes. As a result, non- γ -encoded pulse sequences are sometimes preferable if the largest possible recoupled Hamiltonian is required, and its orientation-dependence is of lesser importance.

The complicated orientation-dependence of non- γ -encoded sequences may also be put to good use. Spiess and co-workers^{68,69} have shown that the orientation-dependence generates characteristic signal modulations in certain two-dimensional experiments. These modulations may be matched with simulations in order to obtain structural information such as internuclear distances. In these applications, the recoupling pulse sequence must *not* be γ -encoded.

A further disadvantage of γ -encoding is that the construction of compensated supercycles is more difficult.

Some recoupled Hamiltonians *cannot* be γ -encoded within the framework of the symmetry theory described here. For example, consider the problem of zero-quantum recoupling in the presence of MAS. Since the selection rules are invariant to an overall sign change, it is not possible to allow terms of the form $\{l, m, \lambda, \mu\} = \{2, m, 2, 0\}$ without also allowing terms of the form $\{2, -m, 2, 0\}$. Since the $\mu = 0$ term is associated with two spatial terms $\pm m$, the resulting Hamiltonian is not γ -encoded. If desired, a γ -encoded zero-quantum DD Hamiltonian may be generated by rotational resonance,^{70–72} which

is based on different principles (see **Rotational Resonance in Biology**, Volume 7).

2.13.3 β -Dependence

Consider the γ -encoded recoupling of dipole–dipole interactions between two spins j and k . Since the DD interaction is symmetrical, the tensor components $[A_{2m}^{jk}]^P$, written in the principal axis system of the DD interaction, vanish for the case $m \neq 0$. From equation (33), the recoupled DD interaction between spins j and k has the form

$$\overline{\mathcal{H}}_{2m2\mu}^{jk}(t^0) = \kappa_{2m2\mu} [A_{20}^{jk}]^P d_{0m}^2(\beta_{PR}^{jk}) \times \exp\{-im(\gamma_{PR}^{jk} + \alpha_{RL}^0 - \omega_r t^0)\} T_{2\mu}^{jk} \quad (41)$$

Here β_{PR}^{jk} and γ_{PR}^{jk} are Euler angles relating the principal axis frame of the DD interaction to the rotor-fixed frame. For example, β_{PR}^{jk} is the angle subtended by the internuclear $j \rightarrow k$ vector and the rotation axis of the sample.

If the sequence implements γ -encoded recoupling, then equation (41) contains the entire orientation-dependence of the $T_{2\mu}^{jk}$ spin operator. As may be seen, the magnitude of the recoupled Hamiltonian depends on β_{PR}^{jk} according to the reduced Wigner function $d_{0m}^2(\beta_{PR}^{jk})$.

The relevant functions have the following form:

$$\begin{aligned} d_{00}^2(\beta) &= \frac{1}{2}(3 \cos^2 \beta - 1) \\ d_{0\pm 1}^2(\beta) &= \pm \sqrt{\frac{3}{8}} \sin 2\beta \\ d_{0\pm 2}^2(\beta) &= \sqrt{\frac{3}{8}} \sin^2 \beta \end{aligned} \quad (42)$$

The type of orientation-dependence may be selected by choosing the m -value of the symmetry-allowed component.

For example, consider the double-quantum recoupling sequences with symmetry $C7_2^1$. As discussed above, this symmetry implements γ -encoded recoupling with selection of the $\{l, m, \lambda, \mu\} = \{2, 1, 2, 2\}$ and $\{2, -1, 2, -2\}$ terms. Since the $m = \pm 1$ terms are symmetry-allowed, the magnitude of the recoupled Hamiltonian is proportional to $d_{01}^2(\beta_{PR}^{jk})$, and hence depends upon orientation according to the function $\sin(2\beta_{PR}^{jk})$. The recoupling effect is maximized at the angles $\beta_{PR}^{jk} = 45^\circ$ and 135° , and vanishes at the orientations $\beta_{PR}^{jk} = 0$ or 180° (internuclear vector along the spinning axis) and also $\beta_{PR}^{jk} = 90^\circ$ (internuclear vector perpendicular to the spinning axis). A sketch of the orientation dependence of the $C7_2^1$ recoupled Hamiltonian is shown in Figure 7(a).

The symmetry $C8_3^1$, on the other hand, implements γ -encoded double-quantum recoupling with selection of the terms $\{l, m, \lambda, \mu\} = \{2, -2, 2, 2\}$ and $\{2, 2, 2, -2\}$. In this case, the magnitude of the recoupled Hamiltonian is proportional to $d_{02}^2(\beta_{PR}^{jk})$, and hence depends upon orientation according to the function $\sin^2(\beta_{PR}^{jk})$. In this case, the recoupling effect is maximized at the angle $\beta_{PR}^{jk} = \pi/2$ (internuclear vector perpendicular to the spinning axis) and vanishes for the angles $\beta_{PR}^{jk} = 0$ and π (internuclear vector parallel to the spinning axis). A sketch of the orientation dependence of the $C8_3^1$ recoupled Hamiltonian is shown in Figure 7(b).

These orientation-dependences may be exploited in the magic-angle spinning of oriented materials.^{55,56,73–75} Glaubit has proposed a series of different recoupling experiments, in order to deduce the angles subtended by internuclear vectors and the spinning axis with a minimum of ambiguity.⁷⁵ This should enhance the molecular structural information which may be obtained from the magic-angle spinning NMR of oriented samples.

The symmetry-aided manipulation of orientation-dependence may also be useful in the NMR of disordered samples such as powders. It is possible to gain information on the relative orientation of pairs of interactions by correlating them with each other using multiple-dimensional NMR methods.^{43,44,76–81} It should be possible to enhance the information content of such experiments, and resolve ambiguities, by using combinations of recoupling symmetries applied in different time intervals of a multidimensional experiment. At the moment, such experiments are still in the planning stage.

2.14 Phase-Time Relationships

The spin tensors transform in the following way when rotated about the z -axis:

$$\exp\{-i\phi I_z\} T_{\lambda\mu}^\Lambda \exp\{-i\phi I_z\} = T_{\lambda\mu}^\Lambda \exp\{-i\mu\phi\} \quad (43)$$

This equation may be combined with equation (40) to obtain the dependence of a recoupled Hamiltonian term on the orientational angles γ_{MR} and α_{RL}^0 , the rf phase ϕ , and the initial time point t^0 :

$$\begin{aligned} \overline{\mathcal{H}}_{lm\lambda\mu}^\Lambda(\gamma_{MR}, t^0, \alpha_{RL}^0, \phi) &= \overline{\mathcal{H}}_{lm\lambda\mu}^\Lambda(0, 0, 0, 0) \\ &\times \exp\{-i[m(\gamma_{MR} + \alpha_{RL}^0 - \omega_r t^0) + \mu\phi]\} \end{aligned} \quad (44)$$

As discussed in Ref.⁸², this relationship may be used to remove the dependence of the recoupled Hamiltonian on the initial time point t^0 . The desired effect is achieved for the case $\mu \neq 0$ by shifting the overall rf phase according to the formula:

$$\phi = \frac{m}{\mu} \omega_r t^0 \quad (45)$$

If this is done, then the average Hamiltonian term $\overline{\mathcal{H}}_{lm\lambda\mu}^\Lambda$ is independent of the initial time point t^0 at which the pulse sequence starts. Equation (45) is called a *phase-time relationship*.

In general, the recoupled Hamiltonian contains many symmetry-allowed terms, which may have different ratios of m and μ . If that is the case, then the formula in equation (45) cannot be implemented simultaneously for all of them, and it is impossible to compensate the full recoupled Hamiltonian for a change in the timing by a shift in the rf phase. This is clearly the case if the sequence is not γ -encoded.

If the sequence is γ -encoded, and if all the symmetry-allowed terms have the same ratio m/μ , then the pulse sequence may be applied at arbitrary time points in a pulse sequence, providing the overall rf phase is adjusted according to equation (45). This is an important practical principle of γ -encoded recoupling sequences, which has been applied in many different experimental contexts.^{39,60,79,82–84}

A typical application is two-dimensional double-quantum spectroscopy. The pulse sequence consists of a preparation period, which may consist of a CN_n^v recoupling sequence, followed by a variable evolution interval t_1 , followed by a mixing interval, which might be a second CN_n^v sequence, followed by signal detection.

In solution NMR, it is possible to vary the evolution interval t_1 in arbitrarily small steps, in order to obtain a sufficiently large spectral bandwidth in the double-quantum dimension. This is because the operation of the preparation and mixing sequences is independent of the times at which they are applied.

In magic-angle-spinning solid-state NMR, on the other hand, the situation is completely different, since the rotation of the sample modulates the spin Hamiltonian during the pulse sequence. In general, the average Hamiltonian generated by the second recoupling sequence depends on the time at which it is applied, and hence on the interval t_1 . As a result, multi-dimensional experiments often display strong periodic modulations in the indirectly-detected dimension, which are due to the rotation of the sample during t_1 (see **Double-Quantum NMR Spectroscopy of Dipolar Coupled Spins Under Fast Magic-Angle Spinning**). It is easy to misinterpret these modulations as being due to the evolution of coherences in the interval t_1 .

If the sequence is not γ -encoded, the only way to avoid these orientational modulations is to restrict t_1 to be integer multiples of a rotor period, so that the sample has the same orientation at the beginning and end of the evolution interval. However, this is a very strong restriction which in many cases greatly cramps the spectral width.

However, if the sequence is γ -encoded, and if all symmetry-allowed terms have the same ratio m/μ , then it is possible to vary the evolution interval completely freely by coupling the rf phase to the timing, according to the phase-time relationship equation (45). This allows multiple-quantum spectroscopy with an arbitrarily large bandwidth in the indirectly-detected dimension. Examples, including explicit formulae for the radio-frequency phases, are given in Refs.^{39,60,79,82–84}

2.15 Incomplete Cycles

As mentioned before, the average Hamiltonian theory is strictly valid only for integer multiples of complete CN_n^v or RN_n^v cycles, i.e., complete multiples of n rotor periods. However, in most cases, the theory seems to work very well even when the full cycles are not completed. This allows a further degree of freedom in experimental design, since it becomes possible to adjust the recoupling intervals in relatively fine time steps.

This is an important advantage in experiments which aim to measure the magnitude of recoupled interactions. A fine time resolution of the recoupling interval is often a prerequisite for obtaining a result of the desired accuracy. Fine time resolution also makes it easier to maximize signal strength in multiple-quantum-filtering experiments.

There is an important complication associated with the use of incomplete recoupling cycles. In general, the pulse sequence propagator under a recoupling sequence is the product of two terms (equation (22)). The first term is the propagator for the rf field under the pulse sequence, while the second term concerns the average Hamiltonian of the internal spin

interactions, which is subject to the selection rules discussed above. In the case of *complete* CN_n^v or RN_n^v sequences, the first term may be omitted, since the complete sequence behaves as a cycle, with an rf propagator proportional to the unity operator. However, this is not always the case for *incomplete* pulse sequences.

The CN_n^v sequences present few problems in this respect, since the rf propagator for an incomplete CN_n^v sequence is still proportional to the unity operator, providing that integer numbers of C elements are completed. As a result, only the average Hamiltonian must be taken into account for integer multiples of C elements.

Matters are more complicated for RN_n^v sequences. If q elements R are completed, the rf propagator is given by

$$U_{\text{rf}}(t^0 + q\tau_R, t^0) = \exp\{-i2q\phi I_z\} \exp\{-iq\pi I_x\} \quad (46)$$

where I_x and I_z is the longitudinal angular momentum operator of the irradiated spins, and the phase ϕ is given ideally by $\phi = \pi v/N$. The duration of each element is $\tau_R = n\tau_r/N$, where τ_r is a rotor cycle.

In the case of even q , the rf propagator leads to an additional z -rotation of the spin operators, which must be taken into account by a compensatory rf phase shift of subsequent rf pulses. This phase shift must be added to the phase shifts imposed by the phase-time relationships, described above, as well as any phase shifts required in the phase cycling procedure, used to select NMR signals passing through certain orders of spin coherence.

In the case of odd q , there is a rotation of the spins by an odd multiple of π about the x -axis, as well as the phase rotation by $2q\phi$. The additional x -rotation may be taken into account by changing the *sign* of subsequent rf phases.

The overall implementation of these multiple phase shifts and phase inversions is quite complex. Refs.^{39,60,79,82–84} give some practical examples with explicit formulae for the rf phases.

If these phase factors are taken into account correctly, it is possible to achieve fine time resolution of both the duration of the recoupling sequences and the intervals between them. In many cases, this is a decisive practical advantage.

2.16 Supercycles

In many cases, the performance of the recoupling sequences is enhanced by *supercycling*, which means repetition of the sequence with some variation of the rf phase shifts or the order of the pulse sequence elements.

The effect of supercycling is well understood on the level of the first-order average Hamiltonian. The higher order effects of supercycling, on the other hand, are currently not well researched, despite their importance. Some of the results sketched below should be regarded as preliminary. Refs.^{39,60} contain some relevant theory.

Most of the supercycles used so far fall into the categories summarized below:

2.16.1 180° Phase Shift Supercycles

If a complete CN_n^v or RN_n^v sequence is repeated with a 180° phase shift, we get a two-step supercycle denoted $[S]_0[S]_{180}$.

Here $[S]_\phi$ indicates an overall phase shift of all elements in the sequence S by the angle ϕ .

This supercycle cancels all components with odd values of μ in the first-order average Hamiltonian. The supercycle therefore implements an additional selection rule which is superimposed on the CN_n^ν or RN_n^ν selection rules.

For example, the symmetry $C5_2^1$ implements γ -encoded double-quantum homonuclear recoupling, with selection of the $\{l, m, \lambda, \mu\} = \{2, \pm 1, 2, \pm 2\}$ terms, similar to $C7_2^1$. However, $C5_2^1$ symmetry also allows CSA terms with quantum numbers $\{2, \pm 2, 1, \mp 1\}$ and single-quantum DD terms with quantum numbers $\{2, \pm 2, 2, \mp 1\}$. These undesirable terms all have odd values of μ and may be suppressed by building a supercycle of the form $[C5_2^1]_0[C5_2^1]_{180}$. The resulting sequence is called SPC5.⁴⁰ It has the same first-order average Hamiltonian properties as $C7_2^1$ but lower rf field requirements.⁴⁰ There are other ways of achieving the same result.³⁹

Supercycles of the form $[S]_0[S]_{180}$ may be used whenever the desired components of the first-order average Hamiltonian have even values of μ . Even when this supercycle does not add to the selectivity of the first-order average Hamiltonian, it tends to reduce higher-order terms. For example, the CSA compensation of RN_n^ν sequences for homonuclear double-quantum recoupling is improved by using supercycles of the form $[RN_n^\nu]_0[RN_n^\nu]_{180}$.⁸⁵

2.16.2 120° Phase Shift Supercycles

A higher degree of coherence order selectivity is implemented by using three-step phase cycles of the form $[S]_0[S]_{120}[S]_{240}$. Supercycles of this type suppress all terms in the average Hamiltonian in which μ is not an integer multiple of 3. Since all spin interactions have μ values between 2 and -2 , this supercycle $[S]_0[S]_{120}[S]_{240}$ selects the $\mu = 0$ components in the average Hamiltonian, suppressing single-quantum and double-quantum terms.

This type of supercycle is useful for stabilizing zero-quantum recoupling sequences such as $R4_4^1$.⁶⁵

2.16.3 Phase Inversion Supercycles

A different effect is achieved by supercycles of the form SS' , where S' indicates the sign reversal of all rf phase shifts in the sequence S . For example, if S consists of a RN_n^ν sequence based on the elements $\mathcal{R} = 90_{-45}90_{45}90_{-45}$ and $\mathcal{R}' = 90_{45}90_{-45}90_{45}$, then S' consists of a RN_n^ν sequence based on the elements $\mathcal{R} = 90_{45}90_{-45}90_{45}$ and $\mathcal{R}' = 90_{-45}90_{45}90_{-45}$.

This type of supercycle replaces first-order average Hamiltonian terms of the form $aT_{\lambda\mu} + a^*T_{\lambda-\mu}$ by the expression $Re\{a\}(T_{\lambda\mu} + T_{\lambda-\mu})$. The effect is to convert the phase modulation of the average Hamiltonian into an amplitude modulation.

This type of supercycle cannot be used for γ -encoded sequences, but has been used with advantage for zero-quantum recoupling sequences, which cannot be γ -encoded.⁶⁵ It is used in many popular implementations of REDOR^{26,27} and RFDR.^{33,34}

2.16.4 Combined Phase Inversion and 180° Pulse Insertion Supercycles

It is possible to combine phase inversion with the insertion of strong 180° pulses, leading to supercycles of the form

$S\Pi_0S'\Pi_{180}$, where Π_ϕ indicates the insertion of a strong, short, 180° pulse of phase ϕ .

If the inserted 180° pulses are ideal and infinitely short, this supercycle maintains the γ -encoding of the average Hamiltonian and also deletes average Hamiltonian terms with odd values of the spin rank λ . This type of supercycle is particularly useful for improving the chemical shift compensation of a pulse sequence.

Tycko used this type of supercycle to compensate ‘zero-field in high-field’ experiments for chemical shifts.^{28,29}

In practice, 180° pulse insertion supercycles are awkward to implement, especially at high spinning frequencies, because the finite duration of real 180° pulses disturbs the timing of the other pulse sequence elements, breaking the pulse sequence symmetry.

2.16.5 Combined Phase Inversion and Cyclic Permutation Supercycles

A similar effect to the insertion of strong 180° pulses is achieved by *cyclically permuting* a 180° pulse sequence element. For example, the cyclic permutation of a 180° element $\mathcal{R}$ of the phase-inverted cycle S' may be denoted $\mathcal{R}^{-1}S'\mathcal{R}$, where the notation $\mathcal{R}^{-1}S'$ indicates the deletion of the element $\mathcal{R}$ from the beginning of the sequence S' .

For example, consider a $C14_4^5$ sequence based on the simple element $\mathcal{C} = 360_0$, i.e.,

$$S = 360_0 360_{128.57} 360_{257.14} 360_{25.71} 360_{154.29} 360_{282.86} 360_{51.43} - \\ 360_{180} 360_{308.57} 360_{77.14} 360_{205.71} 360_{334.29} 360_{102.86} 360_{231.43} \quad (47)$$

spanning four rotational periods. The phase inverted cycle S' is as follows:

$$S' = 360_0 360_{231.43} 360_{102.86} 360_{334.29} 360_{205.71} 360_{77.14} 360_{308.57} - \\ 360_{180} 360_{51.43} 360_{282.86} 360_{154.29} 360_{25.71} 360_{257.14} 360_{128.57} \quad (48)$$

The sequence $\mathcal{R}^{-1}S'\mathcal{R}$ derived by cyclically-permuting the element $\mathcal{R} = 180_0$ of S' is therefore

$$\mathcal{R}^{-1}S'\mathcal{R} = 180_0 360_{231.43} 360_{102.86} 360_{334.29} 360_{205.71} 360_{77.14} 360_{308.57} - \\ 360_{180} 360_{51.43} 360_{282.86} 360_{154.29} 360_{25.71} 360_{257.14} - \\ 360_{128.57} 180_0 \quad (49)$$

This type of supercycle has almost the same effect as the combined phase inversion/180° pulse insertion supercycle discussed above. At the same time there is no need to apply very strong rf pulses. The timing complications associated with the inevitably finite duration of ‘strong’ pulses are also avoided.

The cyclic permutation of an element creates a shift in the timing of the second sequence, disturbing the symmetry. In the case of γ -encoded pulse sequences, the timing shift may be compensated by modifying the rf phase of the second cycle, according to the phase-time relationship (equation (45)). This leads to the modified supercycle $[S]_0[\mathcal{R}^{-1}S'\mathcal{R}]_\delta$, where the overall phase shift δ is given by

$$\delta = -\frac{m}{\mu}\omega_r\tau_{\mathcal{R}} \quad (50)$$

Here τ_R is the duration of the cyclically permuted element $\mathcal{R}$, and m/μ is the ratio of space and spin quantum numbers selected by the γ -encoded CN_n^ν sequence.

In the case of equation (49), the symmetry $C14_4^5$ selects the rotational components $\{l, m, \lambda, \mu\} = \{2, \pm 1, 2, \mp 2\}$, and the permuted element has a duration $\tau_P = 2\tau_r/7$. The phase correction is therefore $\delta = \pi/7 = 25.71^\circ$. The supercycle is

$$\begin{aligned}
 [S]_0[\mathcal{R}^{-1}S'\mathcal{R}]_\delta = & 360_0 360_{128.57} 360_{257.14} - \\
 & 360_{25.71} 360_{154.29} 360_{282.86} 360_{51.43} 360_{180} - \\
 & 360_{308.57} 360_{77.14} 360_{205.71} 360_{334.29} 360_{102.86} - \\
 & 360_{231.43} 180_{25.71} 360_{257.14} 360_{128.57} 360_0 - \\
 & 360_{231.43} 360_{102.86} 360_{334.29} 360_{205.71} - \\
 & 360_{77.14} 360_{308.57} 360_{180} 360_{51.43} 360_{282.86} - \\
 & 360_{154.29} 180_{25.71} \quad (51)
 \end{aligned}$$

This comprises one half of the SC14 sequence.³⁹

This type of supercycle has beneficial effects on the CSA compensation of recoupling sequences, without destroying the γ -encoding.

2.16.6 Additional Supercycles

It is possible to construct supercycles by using consecutive CN_n^ν sequences based upon different basic elements $\mathcal{C}$. For example, Rienstra et al.³⁸ concatenated a $C7_2^1$ sequence based upon the basic cycle $\mathcal{C}_a = 360_0 360_{180}$ with a second $C7_2^1$ sequence based upon a different basic cycle $\mathcal{C}_b = 180_0 360_{180} 180_0$. Some higher-order error terms of the individual cycles cancel out in the mixed supercycle $C7_2^1(a)C7_2^1(b)$.

More complex supercycles may be created by superimposing the basic supercycle types, and by transposing, mixing, and permuting the elements. For example, the full SC14 supercycle³⁹ is

$$[[S]_0[\mathcal{R}^{-1}S'\mathcal{R}]_\delta]_0[[S]_0[\mathcal{R}^{-1}S'\mathcal{R}]_\delta]_{180} \quad (52)$$

where S is a $C14_4^5$ sequence using the basic element $\mathcal{C} = 360_0$, the element $\mathcal{R} = 180_0$ is cyclically permuted, and $\delta = 25.71^\circ$. The CMR7 sequence³⁸ employs a particularly complicated supercycle structure.

At the moment, an empirical approach to supercycle construction prevails, since a complete higher-order theory has not yet been developed.

Supercycling should be implemented with care. In many cases, the supercycles are unnecessary, and readily harm the pulse sequence performance if they are used incorrectly.

2.17 Rf Imperfections

In practice, all rf pulse sequences are subject to various types of instrumental imperfection. Some typical imperfections of practical importance are:

1. Spatial inhomogeneity in the *amplitude* of the rf field over the sample volume;
2. Spatial inhomogeneity in the *direction* of the rf field over the sample volume, which translates into a phase modulation of the rf field as the sample rotates;^{25,86,87}

3. Transients in the rf field upon changes in the driving field amplitude or phase, caused by the limited frequency bandwidth of the probe;^{85,88}
4. Instability or droop in the rf field applied to the probe;
5. Errors in the values of rf phase shifts;
6. Phase instability of the rf field.

Many of these imperfections have been investigated rather thoroughly, and some fit well into the framework of the symmetry theory. In particular, rf amplitude inhomogeneity may be included by using a set of interaction frame Hamiltonian terms with the quantum numbers $l = 0, m = 0, \lambda^{\text{eff}} = Z_g$ and $\mu = \{-1, 0, +1\}$. Here λ^{eff} is the ‘effective spin rank’ of the rf inhomogeneity terms and Z_g is any *even* integer (‘g’ stands for *gerade*, which means ‘even’ in German).

It is surprising that the ‘effective spin rank’ λ^{eff} of the rf inhomogeneity terms is *even*, since the rf spin Hamiltonian actually contains rank 1 spin operators. This is because the rf inhomogeneity terms depend on the phase of the rf field, even before transformation into the interaction frame. As a result, these terms behave differently to the others.⁸⁹

The rf inhomogeneity terms may be inserted into the selection rules and space-spin selection diagrams in the usual way. For example, it is easy to see that the rf inhomogeneity term $\{l, m, \lambda^{\text{eff}}, \mu\} = \{0, 0, Z_g, 0\}$ is symmetry-allowed under $C7_2^1$ and $R18_7^1$ sequences, while the terms $\{0, 0, Z_g, \pm 1\}$ are symmetry-forbidden. In order to achieve first-order rf compensation, one must therefore set the scaling factors for the symmetry allowed $\{0, 0, Z_g, 0\}$ terms to zero. This may be done by using amplitude-modulated basic elements $\mathcal{C}$ or $\mathcal{R}$. It follows that symmetries such as $C7_2^1$ and $R18_7^1$ have first-order compensation for rf inhomogeneity if they are based on amplitude-modulated elements.

In practice, higher-order terms are very important in determining the robustness of a pulse sequence with respect to rf amplitude deviations. These terms may be analyzed by using the selection rules equations (31) and (32). In many cases, it is simpler to use crude geometric arguments as a guideline.³⁹ For example, although the symmetry $C7_2^1$ is compensated for rf amplitude errors to first order (in the case of amplitude-modulated basic elements), geometrical arguments show that the second-order rf error terms are large.³⁹ As a result, $C7_2^1$ sequences must usually be based on elements which have a built-in rf error compensation, such as the original element $\mathcal{C} = 360_0 360_{180}$,³⁶ or the ‘POST’ element $\mathcal{C} = 90_0 360_{180} 270_0$.³⁷ In Ref.³⁹ it is shown by geometrical arguments that the symmetry $C14_4^5$ has a higher degree of intrinsic rf error compensation, and that it is therefore feasible to use this symmetry together with the uncompensated basic element $\mathcal{C} = 360_0$. This provides a two-fold reduction in the rf field requirements for a given spinning frequency.

The effect of rf transients has also been analyzed.⁸⁵ A combination of electronic simulations and experimental measurements has led to the development of a simple analytical model for the transient behavior of the rf field at the sample. This model was used for accurate spin dynamical simulations during symmetry-based sequences, including the transient probe response. The effect of transients is minor, at least in the cases examined so far.

There is one common spectrometer imperfection which is a cause for real concern. In many contexts, the RN_n^ν class of

pulse sequences is extremely sensitive to the precise value of the rf phase shift. As described above, RN_n^ν sequences are composed of elements with the alternating phase values $\pm\pi\nu/N$. Even small deviations from this precise phase shift value may be disastrous.⁸⁵ A phase shift accuracy of $\pm 0.1^\circ$ or better is necessary for many applications of RN_n^ν sequences. In particularly demanding applications, such as long-range distance measurements, the phase shift accuracy should be an order of magnitude better still. Such extreme accuracy stretches current rf hardware. At the moment, only direct digital synthesis (DDS) of the rf wave produces sufficiently reliable and accurate phase shifts. Unfortunately, not all commercial spectrometers are equipped with such devices.

The extreme phase-shift sensitivity of RN_n^ν sequences may be understood using equation (46). This equation shows that a complete RN_n^ν sequence rotates resonant spins about the z -axis through the angle $2N\phi$. Since the value of the phase shift is ideally $\phi = \pi\nu/N$, the overall rotation angle generated by one RN_n^ν sequence is ideally $\Phi = 2\pi\nu$ radians. This is an integer multiple of 360° , and so has no effect on the spin system. If a set of K consecutive RN_n^ν sequences are applied, the overall rotation is through an angle $\Phi = 2\pi\nu K$, which also has no effect. However, if the value of ϕ is in error by a small angle Δ , then the overall rotation over K cycles is in excess by the angle $2NK\Delta$. For example, in the case of a $R14_2^\nu$ sequence, a phase deviation of only $\Delta = 0.1^\circ$ leads to an accumulating error of 2.8° per complete RN_n^ν sequence. Since a typical short-range pulse sequence employs around five complete sequences, the accumulated error rotation is about 14° . This is enough to degrade the double-quantum filtering efficiency significantly, especially since the double-quantum coherences are twice as sensitive as single-quantum coherences to phase shift errors. In a long-range application where around 50 complete sequences are used, the 0.1° phase shift error is disastrous.

CN_n^ν sequences are much less sensitive to phase shift errors, since there are no *accumulating* rotations in this case.

The extreme phase shift sensitivity of RN_n^ν sequences may be removed by using the supercycle SS' . However, this method is only applicable to non- γ -encoded sequences. Work is under way towards a more general solution of this serious practical problem.

2.18 Selection of Sequences

Although the symmetry theory provides a sound framework for the search for suitable pulse sequences, this framework still allows enormous freedom. In order to develop a pulse sequence for a specific task, one must:

- Identify the space-spin components $\{l, m, \lambda, \mu\}$ which must be selected, and those that must be suppressed;
- Identify the set of suitable CN_n^ν or RN_n^ν symmetries;
- Identify the desired range of MAS frequencies;
- Identify a suitable basic element ($\mathcal{C}$ in the case of CN_n^ν symmetry, or $\mathcal{R}$ in the case of RN_n^ν symmetry);
- Identify a suitable supercycle, if required.

For each problem, there are usually a large number of feasible symmetries, and within each symmetry, there is an infinity of possible basic elements.

This great freedom is both a strength and a disadvantage: It is a strength because it allows one to design a sequence tailored to the specific requirements of the experiment; it is a disadvantage because there are too many possibilities for a complete search.

The first two steps are easy: The application itself defines the desired and undesired space-spin components, and it is a straightforward task to identify the set of appropriate symmetries. This may be done manually using space-spin selection diagrams, or by using a Mathematica program⁶³ developed for this purpose (available at <http://www.soton.ac.uk/~mhl>).

The next stage is to choose the symmetry class and the basic element. Here one must pay attention to the following factors:

- The scaling factor for a given basic element $\mathcal{C}$ (or $\mathcal{R}$) under the symmetry class CN_n^ν (or RN_n^ν) should be reasonably high.
- The required rf field depends on the basic element and also the symmetry class (more specifically, the ratio of N to n). If the pulse sequence is intended to be broadband, it is usually desirable that the nutation frequency under the rf field should be as large as possible without being impractically large (see the subject of heteronuclear decoupling, discussed below).
- A rough guide to the relative performance of different symmetries is available by counting the number of symmetry-allowed higher-order terms, using the selection rules in equations (31) and (32).
- It is sometimes unnecessary for the pulse sequence symmetry to suppress all of the undesired rotational components. Undesired components may also be suppressed by using a basic element which provides a zero scaling factor for the undesired rotational components. Supercycling may also be used to suppress the undesired symmetry-allowed components. These strategies are used in the SPC5⁴⁰ and C-REDOR⁶⁷ schemes.

Previous experience in designing composite pulses^{7–9,61,62} has been useful for guiding the choice of $\mathcal{C}$ and $\mathcal{R}$ elements (see **Composite Pulses**, Volume 2). For example, the composite pulse $360_0 360_{180}$ is known to be a robust rf cycle with good rf amplitude compensation and reasonably broadband behavior with respect to isotropic chemical shifts. Its chemical shift performance may be enhanced considerably by cyclically-permuting a 90_0 pulse, leading to $\mathcal{C} = 90_0 360_{180} 270_0$. This ‘permutationally offset-stabilized’ (POST) element is a stalwart of liquid-state broadband decoupling experiments,^{7–9} and was used in the design of the POST-C7 sequence.³⁷ Similarly, the element $\mathcal{R} = 90_0 270_{180}$ is known as an offset-compensated 180° composite pulse,^{7–9,61,62} and often proves to be a good choice in the context of RN_n^ν sequences.^{41,60}

More recently, semi-automated computer searches have been used to identify suitable sequences. For example, Brinkmann⁶⁰ developed a combinatorial approach in which a large number of combinations of feasible symmetries, basic elements, and supercycle schemes are tested numerically by simulation under a variety of test situations.

The future may see a move towards more sophisticated basic elements, employing smoothly modulated pulse shapes rather than rectangular pulses. A full flowering of this field may require further improvements in the speed and flexibility of the electronic hardware.

3 HETERONUCLEAR SEQUENCES

In practice, most samples contain several nuclear spin species. The selection rules and design principles may be extended to the case of heteronuclear spin interactions.

3.1 Heteronuclear Spin Interactions

Suppose that the rotating sample contains two interacting spin species, denoted I and S , which are subjected to resonant rf fields at the corresponding nuclear Larmor frequencies. The nuclear spin interactions may be classified in terms of their spherical ranks under spatial (molecular) rotations, rotations of the I -spin polarizations by rf fields, rotations of the S -spin polarizations by rf fields, and rotations of the external magnetic field. The corresponding classification scheme is shown in Table 3. As may be seen, all interactions, with the exception of the homonuclear J -couplings, have different rotational properties. The symmetry theory of homonuclear rotor-synchronized pulse sequences is extended to the heteronuclear case by employing two different sets of spin quantum numbers.

In the presence of rf fields on both spin species I and S , the interaction frame Hamiltonian may be described as a superposition of many rotational components:

$$\mathcal{H}^\Lambda = \sum_{m=-l}^{+l} \sum_{\mu_I=-\lambda_I}^{+\lambda_I} \sum_{\mu_S=-\lambda_S}^{+\lambda_S} \mathcal{H}_{lm\lambda_I\mu_I\lambda_S\mu_S}^\Lambda \quad (53)$$

as listed in Table 4.

The fundamental design task in heteronuclear spin systems is to design pulse sequence symmetries which select a small

number of combinations of these terms, while suppressing others.

3.2 Strong Heteronuclear Decoupling

A common method for heteronuclear decoupling at the same time as homonuclear recoupling involves the application of a CN_n^v or RN_n^v sequence on one channel while a strong resonant rf field is applied to the second channel. If the rf field is strong enough, this suppresses the heteronuclear spin interactions, so that the two spin species are *decoupled* from each other.

If the strong resonant irradiation is on the I -spin channel, the appropriate selection rules are:

Case of CN_n^{vs} sequences with I -spin decoupling:

$$\overline{\mathcal{H}}_{lm\lambda_I\mu_I\lambda_S\mu_S}^{(1)} = 0 \quad \text{if} \quad mn - \mu v_S \neq NZ \quad \text{or if} \quad \lambda_I = 1 \quad (54)$$

Case of RN_n^{vs} sequences with I -spin decoupling:

$$\overline{\mathcal{H}}_{lm\lambda_I\mu_I\lambda_S\mu_S}^{(1)} = 0 \quad \text{if} \quad mn - \mu v_S \neq \frac{N}{2} Z_{\lambda_S} \quad \text{or if} \quad \lambda_I = 1 \quad (55)$$

Empirically, it is found that effective heteronuclear decoupling requires a relatively large ratio of the nutation frequencies of the spins under their corresponding rf fields, i.e., if the decoupling irradiation is applied to the I -spins, while a recoupling sequence is applied to the S -spins, the ratio of nutation frequencies should be at least $|\omega_{\text{nut}}^I/\omega_{\text{nut}}^S| > \sim 3$.³⁸

In the absence of S -spin irradiation, two-pulse phase modulation (TPPM) of the decoupler field usually enhances the quality of the decoupling.¹⁰ This does not usually appear to be the case when an rf field is also applied to the S -spins. Under some circumstances, however, the decoupling quality may be improved by placing the I -spin rf field well off-resonance, so as to approach or satisfy the Lee–Goldburg condition.¹¹ These effects are of great practical importance but are not fully understood.

Since many of the applications of the symmetry-based sequences are in isotopically-labelled organic solids, good heteronuclear decoupling is of great importance. The need for a very strong decoupler field is a strong constraint on the applications of these pulse sequences, since typical NMR probes cannot tolerate simultaneous resonant rf fields on two irradiation channels for very long. A typical practical limit corresponds to nutation frequencies of around 100 kHz

Table 3 Rotational signatures of interactions in heteronuclear systems

Interaction	Space rank, l	I -Spin rank, λ_I	S -Spin rank, λ_S	Field rank
I -Spin isotropic shift	0	1	0	1
I -Spin CSA	2	1	0	1
I -Spin J -coupling	0	0	0	0
I -Spin DD-coupling	2	2	0	0
S -Spin isotropic shift	0	0	1	1
S -Spin CSA	2	0	1	1
S -Spin J -coupling	0	0	0	0
S -Spin DD-coupling	2	0	2	0
IS J -coupling	0	1	1	0
IS DD-coupling	2	1	1	0

Table 4 Components of I and S -spin interactions in the interaction frame of two resonant rf fields, in the case of exact magic-angle spinning

Interaction	Space rank, l	Space components, m	I -Spin rank, λ_I	I -Spin components, μ_I	S -Spin rank, λ_S	S -Spin components, μ_S
I -Spin isotropic shift	0	0	1	$\{-1, 0, 1\}$	0	0
I -Spin CSA	2	$\{-2, -1, 1, 2\}$	1	$\{-1, 0, 1\}$	0	0
I -Spin J -coupling	0	0	0	0	0	0
I -Spin DD-coupling	2	$\{-2, -1, 1, 2\}$	2	$\{-2, -1, 0, 1, 2\}$	0	0
S -Spin isotropic shift	0	0	0	0	1	$\{-1, 0, 1\}$
S -Spin CSA	2	$\{-2, -1, 1, 2\}$	0	0	1	$\{-1, 0, 1\}$
S -Spin J -coupling	0	0	0	0	0	0
S -Spin DD-coupling	2	$\{-2, -1, 1, 2\}$	0	0	2	$\{-2, -1, 0, 1, 2\}$
IS J -coupling	0	0	1	$\{-1, 0, 1\}$	1	$\{-1, 0, 1\}$
IS DD-coupling	2	$\{-2, -1, 1, 2\}$	1	$\{-1, 0, 1\}$	1	$\{-1, 0, 1\}$

for the I -spin channel and around 50 kHz for the S -spin channel, applied for intervals of up to around 20 ms. Since the symmetry-based sequences require a fixed ratio of the nutation frequency to the spinning frequency, the limitation in the tolerable rf power restricts the operational spinning frequency. For example, the C7 pulse sequence is typically limited to spinning frequencies of 7 kHz or less.³⁶

3.3 Single-Channel Sequences

If the rf field is only applied to one spin species, the opportunities for symmetry selection are restricted. For example, if rf fields are applied at the I -spin Larmor frequency, but not at the S -spin Larmor frequency, the S -spin quantum number is restricted to $\mu_S = 0$. In effect, only the first 5 columns in Table 4 are relevant. Under these circumstances, the rotational properties of the I -spin CSA and that of the IS DD coupling are indistinguishable: Both have $l = 2$ and $\lambda_I = 1$. Similarly, the I -spin isotropic shift and that of the IS J -coupling both have $l = 0$ and $\lambda_I = 1$.

The selection rules for symmetry-based pulse sequences with rf irradiation on the I -spin channel are:

Case of $CN_n^{v_I}$ sequences with no S -spin rf fields:

$$\overline{\mathcal{H}}_{lm\lambda_I\mu_I\lambda_S\mu_S}^{(1)} = 0 \quad \text{if } mn - \mu v_I \neq NZ \quad (56)$$

Case of $RN_n^{v_I}$ sequences with no S -spin rf fields:

$$\overline{\mathcal{H}}_{lm\lambda_I\mu_I\lambda_S\mu_S}^{(1)} = 0 \quad \text{if } mn - \mu v_I \neq \frac{N}{2} Z_{\lambda_I} \quad (57)$$

Here Z_{λ_I} is any integer with the same parity as the spin rank λ_I . These are the same as equations (27) and (28). The S -spin quantum numbers λ_S and μ_S are irrelevant.

It follows that if the rf irradiation is restricted to one channel, the same pulse sequences recouple the heteronuclear DD interactions and the CSA interactions of the resonant spins.

3.4 Dual Pulse Sequences

If rf fields are applied at the Larmor frequencies of both spin species, there are many more opportunities for symmetry selection. As described in Ref.⁶⁰ four different symmetry classes may be envisaged, denoted $CN_n^{v_I, v_S}$, $CRN_n^{v_I, v_S}$, $RCN_n^{v_I, v_S}$ and $RN_n^{v_I, v_S}$ Figure 8. The basic elements may be different on the two channels, although they must have the same duration $n\tau_r/N$. The phase shift scheme for the I -spin irradiation follows the usual construction rule for C-sequences (in the case of $CN_n^{v_I, v_S}$ or $CRN_n^{v_I, v_S}$), or for R-sequences (in the case of $RCN_n^{v_I, v_S}$ or $RN_n^{v_I, v_S}$), and depends on the symmetry numbers N , n and v_I . Similarly, the phase shift scheme for the S -spin irradiation follows the construction rule for C-sequences (in the case of $CN_n^{v_I, v_S}$ or $RCN_n^{v_I, v_S}$), or for R-sequences (in the case of $CRN_n^{v_I, v_S}$ or $RN_n^{v_I, v_S}$), and depends on the symmetry numbers N , n and v_S .

The selection rules for dual sequences may be derived by extension of the single-channel case, and are given by the following expressions:⁶⁰

Case of $CN_n^{v_I, v_S}$ sequences:

$$\overline{\mathcal{H}}_{lm\lambda_I\mu_I\lambda_S\mu_S}^{(1)} = 0 \quad \text{if } mn - \mu_I v_I - \mu_S v_S \neq NZ \quad (58)$$

Figure 8 Naming convention for 2-channel heteronuclear pulse sequences

Case of $RCN_n^{v_I, v_S}$ sequences:

$$\overline{\mathcal{H}}_{lm\lambda_I\mu_I\lambda_S\mu_S}^{(1)} = 0 \quad \text{if } mn - \mu_I v_I - \mu_S v_S \neq \frac{N}{2} Z_{\lambda_I} \quad (59)$$

Case of $CRN_n^{v_I, v_S}$ sequences:

$$\overline{\mathcal{H}}_{lm\lambda_I\mu_I\lambda_S\mu_S}^{(1)} = 0 \quad \text{if } mn - \mu_I v_I - \mu_S v_S \neq \frac{N}{2} Z_{\lambda_S} \quad (60)$$

Case of $RN_n^{v_I, v_S}$ sequences:

$$\overline{\mathcal{H}}_{lm\lambda_I\mu_I\lambda_S\mu_S}^{(1)} = 0 \quad \text{if } mn - \mu_I v_I - \mu_S v_S \neq \frac{N}{2} Z_{\lambda_I + \lambda_S} \quad (61)$$

The consequences of these selection rules may be explored by extended space-spin selection diagrams, as described in Ref.⁶⁰ Expressions for the higher-order selection rules, and the dual-channel scaling factors, are also available.⁶⁰

The dual-channel selection rules enable the design of pulse sequences which select interactions on the basis of their full rotational properties, as detailed in Table 4. For example, the symmetry $CR14_3^{2,2}$ suppresses all average Hamiltonian terms except those with the quantum numbers $\{l, m, \lambda_I, \mu_I, \lambda_S, \mu_S\} = \{0, 0, 0, 0, 0, 0\}$ and $\{2, \mp 1, 1, \pm 1, 1, \pm 1\}$. This symmetry therefore enables γ -encoded double-quantum heteronuclear recoupling, with suppression of all homonuclear DD couplings, all chemical shift terms, and all heteronuclear J -couplings.⁶⁰

In principle, the selection rules (equations (58)–(61)) permit the rational design of homonuclear recoupling sequences with simultaneous heteronuclear decoupling. In principle, this approach could avoid the severe power requirements of the strong heteronuclear decoupling method (see above). However, no dual sequences with significant advantages over conventional decoupling methods have been found yet.

4 APPLICATIONS

This section presents a brief summary of some of the published applications of the symmetry theory sketched above.

Sets of symmetry solutions appropriate for a number of different recoupling and decoupling problems are provided. The field is developing rapidly and these descriptions are by no means exhaustive.

4.1 Double-Quantum Homonuclear Recoupling

Double-quantum homonuclear recoupling has a number of important practical applications, including (see **Homonuclear Recoupling Schemes in MAS NMR**, Volume 4 and **Low- γ Nuclei in Solid Samples**):

- Passing signals through double-quantum coherences allows the suppression of signals from isolated spins-1/2. This is particularly useful, for example, in the spectroscopy of multiply- ^{13}C -labelled macromolecules, since the ‘background’ signals from naturally-occurring isolated ^{13}C nuclei are suppressed, allowing the selective observation of the labelled spin clusters.^{31,36,43,44}
- Double-quantum spectroscopy, and double-quantum filtered correlation spectroscopy, are useful for peak assignments.
- Double-quantum coherences are sensitive to the correlations between local magnetic fields. Double-quantum NMR allows the relative orientations of different spin interactions to be determined, and hence the estimation of interbond angles and torsional angles.^{43,44,76–81,90,91}
- Double-quantum recoupling provides a route to the excitation of higher coherence orders.^{81,92–94}

Double-quantum homonuclear decoupling sequences may be classified according to whether or not they provide a γ -encoded recoupled Hamiltonian.

4.1.1 γ -Encoded Double-Quantum Recoupling

Many CN_n^ν symmetries provide γ -encoded double-quantum recoupling. As described above, γ -encoding simplifies the orientation-dependence of the recoupling, improving the clarity of the dipolar oscillations and the efficiency of the double-quantum excitation, and improving the time resolution.

Some of the symmetries achieving γ -encoded double-quantum recoupling selectively recouple the $m = \pm 1$ terms (Table 5), while others recouple the $m = \pm 2$ terms (Table 6). In general, the former are more efficient. The isotropic chemical shift terms are symmetry-allowed so the scaling factors of these terms must be set to zero by a suitable choice of the basic element C . Table 5 includes the symmetry $C7_2^1$, which was initially demonstrated with the basic element $C = 360_0360_{180}$.³⁶ The ‘POST’ element $C = 90_0360_{180}270_0$ is more robust with respect to chemical shift offsets and is now favored.³⁷ The symmetry $C14_4^5$ allows operation at high spinning frequencies, if it is stabilized by the use of supercycles.³⁹ A variant of $C7_2^1$ employing a complex supercycle structure has been described.³⁸ Sequences with the symmetry $C5_2^1$ have also been used, in conjunction with a two-step supercycle to remove the components $\mu = \pm 1$.⁴⁰

The $C7_2^1$ sequences have already been applied to ‘real’ systems, such as membrane proteins. For example, $C7_2^1$ sequences were applied to a $^{13}\text{C}_2$ -labelled sample of the photoreceptor protein bovine rhodopsin, allowing selective observation of the labelled sites with suppression of the background signals

Table 5 A set of CN_n^ν symmetries for γ -encoded homonuclear double-quantum recoupling, with selection of $\{l, m, \lambda, \mu\} = \{2, \pm 1, 2, \pm 2\}$ or $\{2, \pm 1, 2, \mp 2\}$ terms, and suppression of all CSA terms. The isotropic shift term $\{0, 0, 1, 0\}$ and the homonuclear J -coupling $\{0, 0, 0, 0\}$ are also symmetry-allowed. (see **Bacteriorhodopsin & Rhodopsin**, Volume 2). The evolution of the $^{13}\text{C}_2$ double-quantum coherences in the presence of local fields from the neighboring protons allowed determination of a H–C–C–H torsional angle in the retinylidene chromophore.⁴³ A conformational change could be detected in a trapped photointermediate.⁴⁴ The same experiment has also been demonstrated on carbohydrates.^{77,78} The experiment may be extended to allow the determination of ^{15}N – ^{13}C – ^{13}C – ^{15}N torsional angles in peptides and proteins.^{79–81}

If double-quantum recoupling sequences are applied to single-quantum coherences in clusters of more than two spins, triple-quantum coherences are developed.⁹² These triple-quantum coherences may also be used for torsional angle investigations.⁸¹ The double-quantum recoupled spin dynamics in three-spin-1/2 clusters have been investigated by two-dimensional spectroscopy.³⁹ High orders of coherence have been excited by applying $C7_2^1$ sequences to abundant protons.⁹³ The relaxation of zero-quantum coherence has been studied by using a $C7_2^1$ sequence to excite double-quantum coherence,

followed by a coherence transfer into zero-quantum coherence using a selective pulse pair.⁸³

$C7_2^1$ sequences have also been applied to glasses,^{95–98} zeolites,⁹⁹ inorganic phosphates,^{100–102} proteins¹⁰³ and drug molecules.¹⁰⁴

Figure 9 shows a two-dimensional double-quantum ^{13}C spectrum of $[\text{U-}^{13}\text{C}]\text{-L-tyrosine}$, obtained using the SC14 pulse sequence at a spinning frequency of 20 kHz.³⁹ The utility of such spectra for peak assignment is obvious.

There are also a large number of RN_n^v symmetries suitable for γ -encoded double-quantum recoupling. A set of symmetries which selectively recouple the $m = \pm 1$ terms are listed in Table 7. All of these symmetries suppress the isotropic chemical shift terms, and many of them are particularly robust with respect to chemical shift anisotropies. The symmetries $R14_2^6$ and $R22_4^9$ with $\mathcal{R} = 90_{180}270_0$ have been mainly used so far.^{41,85} Measurement of the excitation dynamics of the double-quantum coherences allows the accurate estimation of ^{13}C - ^{13}C

bond lengths and medium-range distances in $^{13}\text{C}_2$ -labelled systems, even in the presence of large CSA interactions.⁸⁵

As discussed above, the orientation-dependence of the recoupling under the $m = \pm 1$ sequences (Tables 5 and 7) is different from that under the $m = \pm 2$ sequences (Table 6). This is expected to improve the information content of the NMR spectroscopy of rotating oriented samples.⁷⁵ Preliminary results have been obtained.¹⁰⁵

4.1.2 Non- γ -Encoded Double-Quantum Recoupling

It is also possible to implement 2Q homonuclear recoupling without γ -encoding. An example is the back-to-back (BABA) recoupling sequence^{102,106–108} which is given by

$$90_0 - \tau - 90_{180}90_{90} - \tau - 90_{270} \quad (62)$$

The rf pulses are assumed to be strong and short and the delay τ is adjusted so that the complete sequence lasts one rotor period. This sequence corresponds to the first two elements of a $C4_2^1$ sequence, using the basic element $\mathcal{C} = 90_0 - \tau - 90_{180}$. The $C4_2^1$ symmetry implements double-quantum recoupling, but also allows many unwanted terms, such as the isotropic chemical shift term $\{l, m, \lambda, \mu\} = \{0, 0, 1, 0\}$, CSA terms of the form $\{l, m, \lambda, \mu\} = \{2, \pm 2, 1, 0\}$, and zero-quantum DD terms of the form $\{l, m, \lambda, \mu\} = \{2, \pm 2, 2, 0\}$. However, the scaling factors for all of these terms vanish if the rf pulses are made infinitely short. In this limit, the only symmetry-allowed terms in the first-order average Hamiltonian are of the form $\{l, m, \lambda, \mu\} = \{2, \pm 1, 2, \pm 2\}$ and $\{2, \pm 1, 2, \mp 2\}$. In the limit of very strong rf fields, BABA therefore implements non- γ -encoded homonuclear DD recoupling with compensation for chemical shifts. Although the lack of γ -encoding has disadvantages, the same property allows the robustness of the sequence to be enhanced by constructing a SS' supercycle, i.e.,

$$\begin{aligned} &90_0 - \tau - 90_{180}90_{90} - \tau - 90_{270}90_0 - \tau - 90_{180} \\ &90_{270} - \tau - 90_{90} \end{aligned} \quad (63)$$

In addition, the absence of γ -encoding causes orientationally-induced modulations in 2D experiments, which may be analyzed in order to estimate internuclear distances.^{68,69} The

Figure 9 Two-dimensional double-quantum spectrum of $[\text{U-}^{13}\text{C}]\text{-L-tyrosine}$, obtained at a field of 9.4 T and a spinning frequency of 20 kHz, using the SC14 pulse sequence. The dashed lines are guides for the eye. (Adapted from Ref.³⁹)

Table 7 A set of RN_n^v symmetries for γ -encoded homonuclear double-quantum recoupling, with selection of $\{l, m, \lambda, \mu\} = \{2, \pm 1, 2, \pm 2\}$ or $\{2, \pm 1, 2, \mp 2\}$ terms, and suppression of all isotropic shift and CSA terms. The homonuclear J -coupling $\{0, 0, 0, 0\}$ is also symmetry-allowed. All inequivalent solutions in the range $N \leq 20, n \leq 10$ and $v \leq 10$ are shown

$R18_4^2$	$R18_4^7$		

Table 8 A set of CN_n^v symmetries for non- γ -encoded homonuclear double-quantum recoupling. The symmetries $C6_2^1$ and $C6_8^1$ suppress all CSA terms and all homonuclear DD terms except $\{l, m, \lambda, \mu\} = \{2, \pm 2, 2, \mp 2\}$ and $\{2, \pm 1, 2, \pm 2\}$. The symmetries $C6_4^1$ and $C6_{10}^1$ suppress all CSA terms and all homonuclear DD terms except $\{l, m, \lambda, \mu\} = \{2, \pm 2, 2, \pm 2\}$ and $\{2, \pm 1, 2, \mp 2\}$. The isotropic shift term $\{0, 0, 1, 0\}$ and the homonuclear J -coupling $\{0, 0, 0, 0\}$ are symmetry-allowed. All inequivalent solutions in the range $N \leq 20, n \leq 10$ and $v \leq 10$ are shown

$C6_2^1$	$C6_4^1$	$C6_8^1$	$C6_{10}^1$
----------	----------	----------	-------------

supercycled version of BABA has been applied to a variety of systems including phosphate networks^{106,107} and glasses.¹⁰⁸

There are several C -symmetries which provide non- γ -encoded 2Q recoupling with suppression of all CSA terms, even in the case of finite rf fields (see Table 8). The isotropic chemical shift terms are readily suppressed by an appropriate choice of the basic element. These C -sequences may provide an alternative to BABA in the case of limited rf field strength.

4.2 Zero-Quantum Homonuclear Recoupling

The radio-frequency-driven recoupling (RFDR) pulse sequence is widely used to transfer longitudinal magnetization between dipolar coupled spin sites in the solid state (see **Homonuclear Recoupling Schemes in MAS NMR**, Volume 4). The most common application is as the mixing interval in a two-dimensional experiment. If the J -couplings are neglected, the 2D spectrum displays cross peaks which indicate the spatial proximity of spin sites.

The most popular version of RFDR employs the so-called XY8 phase scheme.^{33,34} This corresponds to a sequence of strong 180° pulses, spaced at intervals of one rotor period, with rf phases of $\{0, 90, 0, 90, 90, 0, 90, 0\}$. This corresponds to a SS' supercycle of a $R4_4^1$ sequence, with an overall 45° phase shift. This is indeed an appropriate symmetry for zero-quantum homonuclear recoupling, as may be seen from the list of solutions in Table 9. Symmetries such as $R4_4^1$ select terms of the form $\{l, m, \lambda, \mu\} = \{2, \pm 1, 2, 0\}$ and $\{2, \pm 2, 2, 0\}$. The recoupling is not γ -encoded, which harms its efficiency in a

Table 9 A set of RN_n^ν symmetries for recoupling of the $\{l, m, \lambda, \mu\} = \{2, \pm 2, 2, 0\}$ and $\{2, \pm 1, 2, 0\}$ terms with suppression of all other homonuclear DD terms, CSA terms and isotropic shift terms. The homonuclear J -coupling $\{0, 0, 0, 0\}$ is symmetry-allowed. All inequivalent solutions in the range $N \leq 40, n \leq 10$ and $\nu \leq 20$ are shown

$R4_4^1$	$R6_6^1$	$R6_6^2$	$R4_8^1$
$R8_8^1$	$R8_8^3$	$R10_{10}^1$	$R10_{10}^2$
$R10_{10}^3$	$R10_{10}^4$		

non-oriented sample, but the lack of γ -encoding permits the use of the stabilizing supercycle SS' .

The curious aspect of RFDR is that the scaling factor for the symmetry-allowed terms tends to zero in the limit of a strong rf field. Indeed, simulations show that the only reason RFDR works is because of the finite duration of practical rf pulses, interference from chemical shifts,³⁴ and the significant effect of J -couplings (which may even be dominant in some circumstances). Ishii⁶⁴ has given a symmetry-based analysis of RFDR with finite rf pulses, and proposed the use of symmetries such as $R4_4^1$ and $R6_6^1$. Brinkmann and Schmedt auf der Gönne⁶⁵ have demonstrated additional symmetries and explored the use of more complex $\mathcal{R}$ elements in order to allow operation at high spinning frequencies. One recommended sequence involves the supercycle $[SS']_0[SS']_{120}[SS']_{240}$ where S is a $R6_6^2$ sequence using the

Figure 10 Two-dimensional correlation spectrum of $[U-^{13}C]$ -L-tyrosine, obtained at a field of 9.4 T and a spinning frequency of 23 kHz, using a supercycled $R6_6^2$ pulse sequence, with a mixing interval of 9.9 ms. (Adapted from Ref. ⁶⁵)

Table 10 A set of RN_n^ν symmetries for γ -encoded recoupling of the $\{l, m, \lambda, \mu\} = \{2, \pm 2, 2, \pm 1\}$ or $\{2, \pm 2, 2, \mp 1\}$ components of the homonuclear DD couplings with suppression of all other homonuclear DD terms, CSA terms and isotropic shift terms. The homonuclear J -coupling $\{0, 0, 0, 0\}$ is symmetry-allowed. All inequivalent solutions in the range $N \leq 20, n \leq 10$ and $\nu \leq 10$ are shown

Table 16 A set of RN_n^v symmetries for non- γ -encoded zero-quantum recoupling of CSA interactions, with selection of $\{l, m, \lambda, \mu\} = \{2, \pm 2, 1, 0\}$ terms, and suppression of all isotropic shift and homonuclear DD terms. The homonuclear J -coupling $\{0, 0, 0, 0\}$ is also symmetry-allowed. The same solutions implement zero-quantum heteronuclear recoupling if they are applied to only one spin species. All inequivalent solutions in the range $N \leq 20$, $n \leq 10$ and $v \leq 10$ are shown

$R12_3^1$	$R12_3^2$	$R12_3^4$	$R12_3^5$	$R16_4^1$	$R16_4^3$	$R16_4^5$	$R16_4^7$	$R20_5^1$	$R20_5^2$
$R20_5^3$	$R20_5^4$	$R20_5^6$	$R20_5^7$	$R20_5^8$	$R20_5^9$	$R12_9^1$	$R12_9^2$	$R12_9^4$	$R12_9^5$

element $\mathcal{R} = 90_{180}270_0$. An experimental correlation spectrum of $[U-^{13}\text{C}]\text{-L-tyrosine}$ at a spinning frequency of 20 kHz is shown in Figure 10.

4.3 Homonuclear Single-Quantum Recoupling

Table 10 shows a set of symmetries for recoupling the $\mu = \pm 1$ components of the homonuclear DD interaction. These symmetries are expected to be useful in multiple-quantum spin counting experiments.^{93,94,109,110}

4.4 Selection of J -Couplings

Compilations of symmetries appropriate for the selection of homonuclear J -couplings $\{l, m, \lambda, \mu\} = \{0, 0, 0, 0\}$ with suppression of homonuclear DD couplings and chemical shift anisotropies are given in Tables 11 and 12. The RN_n^v symmetries in Table 12 also suppress isotropic chemical shift terms. For the CN_n^v symmetries in Table 11, on the other hand, the scaling factors for the isotropic shift terms must be set to zero by an appropriate choice of $\mathcal{C}$.

These symmetries may be used in through-bond correlation spectroscopy (TOBSY) experiments.^{48–52} The pulse sequence is used as the mixing interval in a two-dimensional experiment; The transfer of longitudinal magnetization generates cross peaks in the 2D spectrum, indicating spin sites with finite mutual J -couplings (see **Through-Bond Experiments in Solids**).

The original pulse sequences of this kind, suggested by Baldus and Meier^{48–52} have symmetries $R6_1^0$ and $R8_1^0$. Two groups^{50,51} have proposed a new range of pulse sequence, operational at higher spinning frequencies, which employ symmetries such as $C9_3^1$, $C9_6^1$ and others included in Table 11. Chan has demonstrated a $R30_{14}^1$ sequence which also has good performance at high spinning frequency.⁵²

4.5 Selection of Isotropic Chemical Shifts

High-resolution isotropic shift spectra may be obtained in solids if all DD couplings and CSA terms are suppressed. In principle, this may be done by sufficiently rapid sample spinning. However, in practice, the required spinning frequencies are usually impractical. A well-designed rf pulse sequence may assist the spatial averaging, leading to acceptable resolution at practical spinning frequencies. The most common applications of such CRAMPS methods are in the high-resolution ^1H NMR of organic powdered solids (see **Line Narrowing Methods in Solids**, Volume 4).

Tables 13 and 14 show symmetry solutions for fast-spinning CRAMPS. All these symmetries suppress the homonuclear DD couplings and the CSA interactions, while allowing some isotropic shift terms. In this application it is particularly important that the scaling factors for the isotropic shift terms are as large as possible. This requires careful design of the element $\mathcal{C}$.

Spiess and co-workers employed $C3_1^0$ and $C4_1^0$ symmetries in fast-spinning CRAMPS experiments, using the known WHH4 cycles^{12,13} as the basic element $\mathcal{C}$.^{46,47} Recently, Madhu and Zhao demonstrated the use of $R18_2^0$ symmetry.¹¹¹ Figure 11 shows an experimental ^1H spectrum obtained at a spinning frequency of 20 kHz with a $R18_2^0$ sequence

Figure 11 ^1H spectrum of monoethylfumarate, obtained at a field of 9.4 T and a spinning frequency of 20 kHz with a $R18_2^0$ sequence. After correcting for the pulse sequence scaling factor, the linewidths of all four peaks are given by approximately 0.9 ppm. (Adapted from Ref.¹¹¹)

constructed from basic elements $\mathcal{R} = 90_{-45}90_{45}90_{-45}$. Note the use of a phase-modulated basic element, in order to enhance the local averaging of the strong homonuclear interactions.

4.6 CSA Recoupling

Table 15 shows a set of symmetries leading to γ -encoded recoupling of CSA interactions, with suppression of isotropic chemical shifts and homonuclear DD couplings. The recoupled average Hamiltonian is transverse, i.e., it has the form $I_x \cos \phi + I_y \sin \phi$.

These sequences could be useful for measuring the CSA principal values of individual sites in coupled spin clusters.

Table 16 shows a set of symmetries leading to recoupling of the zero-quantum ($\mu = 0$) part of the CSA interaction, with suppression of isotropic chemical shifts and homonuclear DD couplings. In this case, the recoupling is not γ -encoded, and the recoupled average Hamiltonian is longitudinal, i.e., proportional to the operator I_z .

4.7 γ -Encoded Heteronuclear Recoupling

The solutions in Table 15 may also be used for the selective γ -encoded recoupling of heteronuclear DD interactions. If these sequences are applied repetitively at the Larmor frequency of one spin species, while the NMR signals from a coupled spin species are observed, the resulting spectrum displays a splitting, due to the recoupled heteronuclear interactions. Since the recoupling is γ -encoded, the splittings are prominent, even in orientationally-disordered systems such as powders.

Zhao has demonstrated the measurement of $^{13}\text{C}\text{-}^1\text{H}$ and $^{15}\text{N}\text{-}^1\text{H}$ DD couplings, using sequences with $R18_1^7$ and $R18_2^5$ symmetries.^{112,113} An experimental example is shown in Figure 12. The figure shows the individual ^{15}N spectra of the two different NH groups in the imidazole ring of L-histidine hydrochloride monohydrate, obtained in a 2D experiment in which a $R18_2^5$ sequence is applied at the ^1H Larmor frequency.¹¹³ There is a visible difference in the two splittings, which corresponds to a 4 pm difference in the two NH bond lengths. This difference is attributed to an intermolecular hydrogen bond formed by one of the NH groups. This result shows the potential of recoupling experiments for investigating the details of intermolecular interactions and other bonding

Table 17 A set of $CRN_n^{v_I, v_S}$ symmetries for γ -encoded double-quantum heteronuclear recoupling, with suppression of all CSA terms, isotropic chemical shift terms, homonuclear DD terms, and heteronuclear J -couplings. All symmetries recouple terms of the form $\{l, m, \lambda_I, \mu_I, \lambda_S, \mu_S\} = \{2, \mp 1, 1, \pm 1, 1, \pm 1\}$. The homonuclear J -couplings $\{0, 0, 0, 0, 0, 0\}$ are symmetry-allowed. All inequivalent solutions in the range $N \leq 20, n \leq 9$ and $N/n \leq 7$ are shown

$CR14_3^{2,2}$	$CR14_3^{-5,-5}$	$CR16_3^{1,4}$	$CR16_3^{-4,-7}$	$CR18_3^{-1,7}$	$CR18_3^{1,5}$

$R16_9^{3,4}$	$R16_9^{-4,-5}$	$R20_9^{-3,-6}$	$R20_9^{-4,-5}$	$R20_9^{4,7}$	$R20_9^{5,6}$

perturbations, in systems that are unsuitable for crystallography or solution NMR.

The symmetry $C5_1^1$ has also been used for γ -encoded heteronuclear recoupling, although it does not fully suppress the homonuclear DD terms.^{114–116} The performance of $C5_1^1$ is acceptable if it is used together with a basic element C with good local averaging properties for the homonuclear DD interactions. The frequency-switched Lee–Goldburg (FSLG)¹⁷ and MREV^{14,15} sequences have both been used.^{114–116} Nevertheless, one expects some interference from the homonuclear DD couplings in the $C5_1^1$ -based methods.

4.8 Non- γ -Encoded Heteronuclear Recoupling

The symmetries in Table 16 lead to zero-quantum recoupling of heteronuclear DD interactions, with suppression of chemical shift terms and homonuclear DD couplings. The recoupled heteronuclear interactions are proportional to the operator product $I_z S_z$.

If the RN_n^v sequence is applied to the I -spin species, the S -spin NMR signals display a splitting which may be used to estimate the magnitude of the heteronuclear DD coupling. Since the recoupling is not γ -encoded, the splittings are relatively obscure in a powder sample.

Although the CSA interactions of resonant spins are recoupled at the same time as the heteronuclear DD interactions, the

influence of the recoupled CSA terms is often minor, since the terms commute. In the single-quantum case of Table 15, on the other hand, the two recoupled interactions do not necessarily commute, and may interfere with each other in a complex way. The solutions in Table 15 are therefore only suitable for the heteronuclear recoupling of spins with small CSA interactions, while the solutions in Table 16 are more generally applicable.

The symmetries in Table 16 may be regarded as extensions of the REDOR pulse sequence.^{26,27} Unlike REDOR, they implement homonuclear dipolar decoupling of the irradiated spin species, and should be applicable to systems with homonuclear dipolar interactions.

REDOR itself consists of two 180° pulses per rotor period, and therefore belongs to the symmetry class $RN_{N/2}^v$. The most common implementation of REDOR follows the XY8 phase scheme, which corresponds to the supercycle SS' of the symmetry $R4_2^1$. This symmetry implements selection of the $\{l, m, \lambda, \mu\} = \{2, \pm 1, 1, 0\}$ terms, just as the solutions in Table 16. However, the $R4_2^1$ symmetry also allows homonuclear DD terms of the form $\{2, \pm 2, 2, 0\}$, $\{2, \pm 1, 2, \pm 2\}$ and $\{2, \pm 1, 2, \mp 2\}$. These recoupled homonuclear DD interactions interfere with the operation of REDOR in non-dilute spin systems, a defect which should be reduced by the symmetries in Table 16.

Chan has discovered a different way of suppressing the homonuclear DD interactions in the REDOR method.⁶⁷ The

Figure 12 (a) Experimental ^{15}N spectrum of the δ_1 nitrogen site of $[\text{U-}^{13}\text{C}, ^{15}\text{N}]\text{-L-histidinium hydrochloride monohydrate}$, obtained by a 2D experiment in the presence of $R18_2^3$ irradiation of the protons, at a magnetic field of 9.4 T and a spinning frequency of 20 kHz. The three-peak structure is due to the recoupled heteronuclear interaction between the ^{15}N and the directly-bonded ^1H . (b) Experimental ^{15}N spectrum of the ϵ_2 nitrogen site. Note that the splitting is slightly larger than in plot (a). These spectra show that the δ_1 NH bond is about 4 pm longer than the ϵ_2 NH bond. This elongation is attributed to the existence of an intermolecular hydrogen bond (see crystal structure in (c)). (Adapted from Ref.¹¹³)

C-REDOR sequences are based upon the symmetries $C3_3^1$ and $C7_7^1$. These symmetries allow heteronuclear DD terms of the form $\{l, m, \lambda, \mu\} = \{2, \pm 1, 1, 0\}$ and $\{2, \pm 2, 1, 0\}$, and also the isotropic chemical shift term $\{0, 0, 1, 0\}$ and homonuclear DD terms of the form $\{2, \pm 1, 2, 0\}$ and $\{2, \pm 2, 2, 0\}$. This does not seem very promising since most of these terms are undesirable. However, by using the POST element $C = 90_0360_{180}270_0$, the scaling factors for all of the symmetry-allowed terms with the exception of $\{2, \pm 1, 1, 0\}$ and $\{0, 0, 0, 0\}$ may be made to vanish. The result is a REDOR-like average Hamiltonian with suppression of homonuclear DD couplings. This has been demonstrated experimentally.⁶⁷

4.9 Double-Quantum Heteronuclear Recoupling by Dual Pulse Sequences

It is also possible to recouple heteronuclear interactions by applying synchronized rf irradiation to both spin species. This procedure allows γ -encoded recoupling of the heteronuclear interactions with the suppression of CSA interference.

The ‘dual’ selection rules in equations (58)–(61) may be used to generate the symmetry solutions. Sets of symmetries suitable for γ -encoded double-quantum heteronuclear recoupling are shown in Table 17 and 18. All of these symmetries recouple the terms of the form $\{l, m, \lambda_I, \mu_I, \lambda_S, \mu_S\} = \{2, \mp 1, 1, \pm 1, 1, \pm 1\}$ with suppression of all isotropic chemical shift, homonuclear DD coupling and CSA terms. In the case of the $CRN_n^{v_I, v_S}$ symmetries in Table 17, the heteronuclear J -couplings are also suppressed.

Brinkmann⁶⁰ has shown that these symmetries may be used for the generation of heteronuclear multiple-quantum coherences, for the measurement of heteronuclear coupling constants, and for implementing magnetization transfer between spin species. For example, a sequence with the symmetry $R24_9^{5,10}$ has been used to obtain a heteronuclear multiple-quantum spectrum of a labelled amino acid.⁶⁰

4.10 Heteronuclear Decoupling

The two-pulse phase modulation (TPPM) decoupling method¹⁰ may also be understood qualitatively using the symmetry theory. The TPPM modulation scheme corresponds to a RN_n^v sequence with a large ratio of N to n , although exact synchronization with the sample rotation does not appear to be important in this case. Edén has shown^{41,45} that in many cases, a similar decoupling quality to TPPM may be achieved with exactly synchronized CN_n^v and RN_n^v sequences, and that the decoupling quality correlates reasonably well with higher-order term counts obtained by applying the rules in equations (31) and (32). In addition, there is evidence that the quality of heteronuclear decoupling is enhanced by implementing homonuclear *recoupling* at the same time, using symmetries such as $R24_2^{1,41}$. This actually happens inadvertently in many implementations of TPPM. This observation is consistent with the well-known effect of ‘self-decoupling’, where strong homonuclear couplings within one spin species can narrow the peaks of a second, coupled, spin species.⁴ (See **Heteronuclear Decoupling in Solids**.)

5 CONCLUSIONS

The symmetry theory sketched here is still in its infancy, although it is already clear that it provides much insight into the operation of many existing pulse sequences, as well as many new experimental possibilities. There remain many theoretical problems, such as the treatment of higher-order terms, and many practical problems, such as the phase-shift sensitivity of the RN_n^v sequences. It is hoped that this summary will encourage many other research groups to explore the subject.

1 INTRODUCTION

In nuclear magnetic resonance (NMR), the magnetic interaction between the nuclear magnetic dipole moment and the magnetic field $\mathbf{B}_0$ determines the nuclear spin energy levels. Nuclear spin interactions with the chemical structures in the local environment cause small shifts of the energy levels. Brownian molecular motions cause this local structure to fluctuate and as a result cause the energy levels to be time dependent. The frequency component of energy level fluctuation at the frequency difference between two energy levels induces nuclear spin transitions between the energy levels. The rate of such transitions depends on the intensity of the nuclear spin energy at the nuclear spin transition frequency. These transitions couple the spin system to the kinetic energy of the molecular system, enabling the spin system to reach thermal equilibrium (i.e. to relax). The relaxation times are inversely proportional to the transition rates. Therefore, we can use NMR relaxation time measurements to study molecular motions in liquids.

In the case of spin- $\frac{1}{2}$ nuclei, the spin interactions include magnetic interactions of the nuclear magnetic moment with the local magnetic field. The local magnetic field depends on the distance and position relative to neighboring nuclear spins and unpaired electrons, and on the effective local fields generated by the chemical shielding due to the surrounding electrons. Nuclei of spin $> \frac{1}{2}$ have an additional interaction, the electric

interaction between the nuclear quadrupole moment and the surrounding electric charges. Both interactions depend on the length of the vector that joins the nucleus to the interacting entity and on the orientation of this interaction vector in the magnetic field $\mathbf{B}_0$. Such interactions are the mechanism by which the energy of the nuclear spins is coupled to the molecular system.

To illustrate the relationship between Brownian motion and NMR relaxation, we consider the cases of magnetic dipolar interaction between two identical spin- $\frac{1}{2}$ nuclei and of electric quadrupolar interaction of a spin 1 nucleus with an electric charge ze . In both instances, the relaxation times are given¹ by the expressions:

$$1/T_1 = H[J_1(\omega_0) + J_2(2\omega_0)] \quad (1)$$

$$1/T_2 = \frac{1}{4}H[J_0(0) + 10J_1(\omega_0) + J_2(2\omega_0)] \quad (2)$$

where T_1 is the spin-lattice relaxation time, T_2 is the transverse of spin-spin relaxation time, and ω_0 is the angular Larmor frequency. These equations apply in the motionally narrowed limit (see **Relaxation Theory: Density Matrix Formulation**) which is appropriate for liquids.

In deriving these relationships, we express the time dependencies of the nuclear spin interactions $\mathcal{H}(t)$ in terms of the interaction constants H and the time correlation functions $\langle F_h(t)F_h^*(t + \tau) \rangle$ in which the $F_h(t)$ terms are the spatial parts of the time-dependent nuclear spin interactions and the $\langle \rangle$ brackets denote ensemble average. The $J_h(\omega)$ terms are Fourier intensities (or spectral densities) of the time correlation functions at the angular frequency ω as given by

$$J_h(\omega) = \int_{-\infty}^{+\infty} \langle F_h(t)F_h^*(t + \tau) \rangle \exp(i\omega\tau) d\tau \quad (3)$$

where $i = (-1)^{\frac{1}{2}}$ and the asterisk denotes the complex conjugate. The interaction constants are $H = (9/8)\gamma^4\hbar^2$ for magnetic dipole-dipole interaction between two identical atomic nuclei and $H = (9/8)e^4Q^2z^2\hbar^2$ for the electric quadrupolar interaction. The physical quantities are: γ , the nuclear magnetogyric ratio; $\hbar$, Planck's constant divided by 2π ; e , the unit electric charge; z , the number of unit charges in the electric charge; and Q , the nuclear quadrupole moment. For both interactions, the $F_h(t)$ terms are related to the second-order spherical harmonics as given by:

$$F_0(t) = r(t)^{-3}[3\cos^2\theta(t) - 1] \quad (4a)$$

$$F_1(t) = r(t)^{-3}\{\sin\theta(t)\cos\theta(t)\exp[i\phi(t)]\} \quad (4b)$$

$$F_2(t) = r(t)^{-3}\{\sin^2\theta(t)\exp[2i\phi(t)]\} \quad (4c)$$

in which $r(t)$ is the length of the vector connecting the nucleus with the interacting unit, and $\theta(t)$ and $\phi(t)$ are the polar and azimuthal angles that describe the orientation of this vector in the laboratory rectangular coordinate system S (magnetic field $\mathbf{B}_0$ of the NMR spectrometer).

Different motions of molecules in liquids cause r , θ , and ϕ to be time dependent. We classify them as rotational and translational. The translational motions cause the molecules to move in three-dimensional space. The rotational motions cause

an axis in the molecule to change in orientation with respect to the axes of the fixed three-dimensional laboratory rectangular coordinate system. Many molecules contain chemical groups that can rotate with respect to the rest of the molecule. Methyl groups that reorient about the methyl threefold symmetry axis comprise a common example of molecular internal motion.

We commonly designate relaxation interactions as *intra-molecular* or *intermolecular*, depending on whether the entity that interacts with the nucleus is part of the same molecule. This designation is related to the above classification of molecular motions. For a completely rigid molecule (Section 3), the intramolecular relaxation results only from the time dependences of θ and ϕ because r is constant. Then, we may remove r from equations (3) and (4) absorb it into a redefined H (i.e. H'), and redefine the $F_h(t)$:

$$F_0(t) = 3 \cos^2 \theta(t) - 1 \quad (5a)$$

$$F_1(t) = \sin \theta(t) \cos \theta(t) \exp[i\phi(t)] \quad (5b)$$

$$F_2(t) = \sin^2 \theta(t) \exp[2i\phi(t)] \quad (5c)$$

For magnetic dipolar relaxation of two identical nuclei with spin- $\frac{1}{2}$, $H' = (9/8)\gamma^4 \hbar^2 r^{-6}$. For quadrupolar relaxation of a nucleus with spin 1, $H' = (9/8)e^4 Q^2 z^2 \hbar^2 r^{-6}$. Here, if all the electric charges result in a nuclear quadrupolar interaction with zero asymmetry parameter, $H' = (9/8)\pi^2 \chi^2$. The same statement applies to intragroup relaxation of nuclei in a rigid group that rotates within an otherwise rigid ellipsoid (Section 4), such as a methyl group that rotates about its threefold symmetry axis that is fixed to the ellipsoid. However, intramolecular magnetic dipolar relaxation between a nucleus of such a rotating group and a nucleus on the remainder of the ellipsoid (Section 5) is more complex. Besides θ and ϕ , r also is time dependent. For intermolecular magnetic dipolar relaxation (Section 7), r , θ , and ϕ are all time dependent. A mathematical description of the correlation function is especially complex. It depends on the translational diffusion of the molecules and on the rotational motions of the molecule. We emphasize intramolecular NMR relaxation in this article and briefly treat intermolecular relaxation in Section 7.

As the NMR relaxation times are related to the molecular motions through the correlation function and the spectral densities, we need relationships between these quantities to analyze the relaxation times of liquids in terms of molecular motions. It is customary to invoke specific models of molecular motions and formulate correlation functions from these models. There are many different models that are based on different starting points and perturbations from them. Some are based on a quantum mechanical formulation and some are treated from the viewpoint of classical mechanics. No single, tractable model that describes all liquids has been found.

2 REMARKS ON MODELS OF MOLECULAR REORIENTATION

Molecules in the gaseous state undergo vibrational and rotational motions and exist in discrete vibrational-rotation energy levels with discrete frequencies. Molecular collisions cause transitions between the energy states and broaden the energy levels. In a condensed phase, such as a liquid

or a solid, the ‘collisions’ between molecules occur much more frequently and the kinetic and potential energies of the different molecules are much more closely coupled. Consequently, we cannot calculate the correlation functions that are effective in NMR relaxation from the motions of isolated, noninteracting molecules. Rothschild² has presented a comprehensive, detailed account of the theoretical and experimental knowledge of the rotational and vibrational motions of small, nearly spherical molecules in liquids.

Many different models of molecular reorientation have been discussed. It is beyond the scope of this article to review these models in detail because the literature is extensive (see *Spin-Rotation Relaxation Theory*). One approach is to start from an assembly of freely rotating molecules, as in a dilute gas. There are different ways of introducing the effects of the surrounding molecules. One way is to have collisions that introduce sudden or instantaneous changes in molecular angular momentum. Another way is to examine the potential energy of the molecule as a function of orientation. If the potential energy is independent of orientation, the molecule experiences no torques and rotates freely. The correlation function is that for an assembly of freely rotating molecules. If the potential energy does depend on orientation, the molecule experiences torques that depend on the molecular shape and on the shape, configuration, motions (‘collisions’), and distances of the neighboring molecules. These torques quench or change the molecular rotation. The effective molecular shape could be that of a spherical top, a symmetric top, or a completely asymmetric rotor. The molecule might experience a constant torque or a torque that is significant only when the neighboring molecules attain specific configurations. In such approaches, the rotational inertia of the molecule is important in deciding the mathematical form of the correlation function.

Another approach is to assume that the environment of the molecule sets up an energy barrier that the molecule must surmount to rotate into an orientation in which its interaction energy with its neighbors is the next minimum. While in this potential well, the molecule undergoes low-amplitude rotational oscillations. A ‘large’ change in orientation occurs when a transition from one potential well to another takes place. The molecule is stationary except for occasional jumps to a different orientation. Some consider the jump to be instantaneous and others consider the jump velocity to be the rms average molecular rotational velocity obtained from kinetic energy considerations.

Clearly the rotational motion of molecules in liquids is a many-body problem and, to calculate the correlation functions, we must introduce approximate methods. We can view Brownian rotational motion as a random walk in coordinate space in which the molecular orientations are defined relative to a motionless laboratory coordinate system. Diffusion-type equations correctly describe the observed rms displacements after many random steps have taken place. The length of the step is an important parameter if solutions of diffusion-type equations are to be used to calculate the correlation functions. The average length of the step must be small compared with the correlation distance of the orientational function. Because the orientational functions undergo large changes with a one-radian change in orientation, the step must be much smaller than one radian.

The Debye theory³ is a widely used model of molecular reorientation. The molecule is assumed to be a rigid sphere that

undergoes isotropic reorientations by infinitesimal rotations caused by thermal collisions with other molecules. Because the reorientation occurs by infinitesimal rotations, isotropic rotational diffusion motion is obtained. The rotational diffusion coefficient is related through Stokes's law to the viscosity of the fluid. This approach was used by Bloembergen, Purcell, and Pound⁴ in their pioneering work on NMR relaxation.

Perrin⁵ has developed an anisotropic model of molecular reorientation. The molecule reorients like a rigid ellipsoid that undergoes rotational diffusion by infinitesimal rotations about the different ellipsoid axes at different rates. Although the diffusion approximation may not be an exact model and molecules are not completely rigid, it does provide a reasonably reliable model for many liquids. Also, use of it yields equations that are well suited for straightforward data reduction. In the following sections, we assume that molecules are rigid bodies that follow the Perrin model and that internal motion is described by rigid groups that rotate about an axis that is fixed to the rigid body. This internal rotation is independent of the ellipsoid reorientation. Some consequences of vibrations and oscillations of the otherwise rigid bodies are noted in Section 8.1.

3 CORRELATION FUNCTIONS FOR A RIGID, COMPLETELY ASYMMETRIC ELLIPSOID

In formulating the spatial orientational correlation functions of nuclei in a completely asymmetric ellipsoid, it is convenient to express the $F_h(t)$ in terms of the direction cosines l , m , and n of the nuclear interaction vector with respect to the X , Y , and Z axes, respectively, of the laboratory coordinate system S . Rotational Brownian motions cause these direction cosines to fluctuate. The coordinate system S is fixed in space with its Z axis in the direction of $\mathbf{B}_0$. Using the definitions $l = \sin \theta \cos \phi$, $m = \sin \theta \sin \phi$, and $n = \cos \theta$, the $F_h(t)$ terms, as given by equation (5) in which r is constant, are:

$$F_0(t) = 1 - 3n^2 \quad (6a)$$

$$F_1(t) = (l + im)n \quad (6b)$$

$$F_2(t) = (l + im)^2 \quad (6c)$$

To include the fluctuations of these direction cosines, we use two additional rectangular coordinate systems. The first is S_0 , a stationary reference frame, to describe the rotational motion of the ellipsoid. The other coordinate system is S' which is fixed to the ellipsoid and oriented such that the X' , Y' , and Z' axes of S' always coincide with the three major axes of the ellipsoid. We reference the direction cosines of the relaxation interaction vector in the ellipsoid directly to S' . At time t , these direction cosines are denoted by l' , m' , and n' . When there is no internal motion, the direction cosines always have these values. However, to allow for internal motion in later equations, we let l'' , m'' , and n'' be the respective direction cosines at the later time $t + \tau$.

We assume that all of the ellipsoids are equivalent. Since we are dealing with liquids, at any instant t there is a random

orientation distribution of ellipsoids. Let us choose a particular ellipsoid. We orient S_0 of this ellipsoid so that, at time t , S_0 coincides with S' and the Euler angles $(\phi_0, \theta_0, \psi_0)$ that describe the orientation of S' in S_0 are all zero. Since S_0 is stationary and S' is fixed to the ellipsoid, rotational Brownian motion of the ellipsoid causes ϕ_0 , θ_0 , and ψ_0 to become nonzero. The direction cosines of the relaxation interaction vector in S_0 at $t + \tau \geq 0$ are given by the following transformation that involves the change in the Euler angles of S' in S_0 :

$$\begin{pmatrix} l_0 \\ m_0 \\ n_0 \end{pmatrix} = \begin{pmatrix} c_{11} & c_{12} & c_{13} \\ c_{21} & c_{22} & c_{23} \\ c_{31} & c_{32} & c_{33} \end{pmatrix} \begin{pmatrix} l'' \\ m'' \\ n'' \end{pmatrix} \quad (7)$$

where

$$\left. \begin{aligned} c_{11} &= \cos \psi \cos \phi - \cos \theta \sin \phi \sin \psi \\ c_{12} &= -\sin \psi \cos \phi - \cos \theta \sin \phi \cos \psi \\ c_{13} &= \sin \theta \sin \phi \\ c_{21} &= \cos \psi \sin \phi + \cos \theta \cos \phi \sin \psi \\ c_{22} &= -\sin \psi \sin \phi + \cos \theta \cos \phi \cos \psi \\ c_{23} &= -\sin \theta \cos \phi \\ c_{31} &= \sin \theta \sin \psi \\ c_{32} &= \sin \theta \cos \psi \\ c_{33} &= \cos \theta \end{aligned} \right\} \quad (8)$$

In this definition of the transformation matrix elements, the subscript of the Euler angles has been omitted for simplicity. Finally, the direction cosines of the interaction vector in S are given by the following transformation in Euler angles (ϕ, θ, ψ) that describe the orientation of S_0 in S :

$$\begin{pmatrix} l \\ m \\ n \end{pmatrix} = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{pmatrix} \begin{pmatrix} l_0 \\ m_0 \\ n_0 \end{pmatrix} \quad (9)$$

where the definitions of the a_{ij} are analogous to those of the c_{ij} in equation (8). We use the transformations shown in equations (7) and (9) to evaluate the functions $F_h(t + \tau)$ for $\tau \geq 0$. The initial conditions imply that $c_{ij}(t) = \delta_{ij}$ (the delta function). Consequently, the initial values at time t are:

$$F_0(t) = 1 - 3(a_{31}l' + a_{32}m' + a_{33}n')^2 \quad (10a)$$

$$F_1(t) = (A_1l' + A_2m' + A_3n')(a_{31}l' + a_{32}m' + a_{33}n') \quad (10b)$$

$$F_2(t) = (A_1l' + A_2m' + A_3n')^2 \quad (10c)$$

where

$$A_1 = a_{11} + ia_{21} \quad (11a)$$

$$A_2 = a_{12} + ia_{22} \quad (11b)$$

$$A_3 = a_{13} + ia_{23} \quad (11c)$$

Because molecular orientations in a liquid are random, there is a random distribution of orientations of S_0 in S . The c_{ij} in all the S_0 are equivalent at all times $t + \tau \geq t$. The rotational Brownian motion of the ellipsoid causes the c_{ij} to be time dependent. Suppose $\Delta\alpha$, $\Delta\beta$, and $\Delta\gamma$ are the angular displacements of the ellipsoid about the X' , Y' , and Z' axes, respectively, of S' due to the Brownian motion. We assume that the elementary angular displacements are sufficiently small (see Section 8.2) so that the angular displacements during time τ are given by rotational diffusion relationships that involve rotational diffusion coefficients R_i as:

$$\langle(\Delta\alpha)^2\rangle = 2R_1\tau \quad (12a)$$

$$\langle(\Delta\beta)^2\rangle = 2R_2\tau \quad (12b)$$

$$\langle(\Delta\gamma)^2\rangle = 2R_3\tau \quad (12c)$$

and the motions are statistically independent, e.g., $\langle\Delta\alpha\Delta\beta\rangle = 0$. Internal motion within the ellipsoids, when it occurs, causes the direction cosines l'' , m'' , and n'' to be time dependent. Because we assume that the internal motion is statistically independent of the Brownian motion of the ellipsoid, we average separately over the two types of motion to obtain the final correlation functions. For each S_0 , and for a given set of intramolecular parameters, the $F_h(t)$ in the correlation function is a time independent multiplication factor and the autocorrelation function becomes:

$$\langle F_h(t)F_h^*(t+\tau) \rangle_{S_0} = F_h(t)\langle F_h^*(t+\tau) \rangle_{S_0} \quad (13)$$

In the calculation of the rotational Brownian motion parts of $\langle F_h^*(t+\tau) \rangle_{S_0}$, we find for each S_0 a sum of terms that are proportional to squares and products of the c_{ij} that appear in the transformation shown in equation (8). To calculate these terms, we use the time dependent probability density $P(\phi_0, \theta_0, \psi_0; \tau)$ for S' to be in orientation $(\phi_0, \theta_0, \psi_0)$ in S_0 at time $t + \tau$. This probability density is described⁶ by the partial differential equation:

$$\partial P(\phi_0, \theta_0, \psi_0; \tau) / \partial \tau = \Lambda P(\phi_0, \theta_0, \psi_0; \tau) \quad (14)$$

where the operator Λ is given by:

$$\begin{aligned} \Lambda = & (R_1 \cos^2 \psi_0 + R_2 \sin^2 \psi_0) \left(\frac{\partial^2}{\partial \theta_0^2} \right) \\ & + (R_1 \sin^2 \psi_0 + R_2 \cos^2 \psi_0) \left(\cot \theta_0 \frac{\partial}{\partial \theta_0} + \frac{1}{\sin^2 \theta_0} \frac{\partial^2}{\partial \phi_0^2} \right. \\ & \left. + \cot^2 \theta_0 \frac{\partial^2}{\partial \psi_0^2} - \frac{2 \cot \theta_0}{\sin \theta_0} \frac{\partial^2}{\partial \phi_0 \partial \psi_0} \right) \\ & + 2(R_1 - R_2) \frac{\cos \psi_0 \sin \psi_0}{\sin \theta_0} \left(\frac{\partial^2}{\partial \theta_0 \partial \phi_0} - \cos \phi_0 \frac{\partial^2}{\partial \theta_0 \partial \psi_0} \right. \\ & \left. + \frac{1 + \cos^2 \theta_0}{2 \sin \theta_0} \frac{\partial}{\partial \psi_0} - \cot \theta_0 \frac{\partial}{\partial \phi_0} \right) \\ & + R_3 \frac{\partial^2}{\partial \psi_0^2} \end{aligned} \quad (15)$$

The properties of Λ are such that the time differential $\langle f \rangle$, the average value of any function f of the orientation of the ellipsoid, is given by the relationship

$$d\langle f \rangle / d\tau = \langle \Lambda f \rangle \quad (16)$$

The application of equation (15) yields:

$$\Lambda(c_{jj}c_{kk} + c_{jk}c_{kj}) = -(4R_i + R_j + R_k)(c_{jj}c_{kk} + c_{jk}c_{kj}) \quad (17)$$

$$\Lambda c_{ri}^2 = -2(R_j + R_k)c_{ri}^2 + 2R_j c_{rk}^2 + 2R_k c_{rj}^2 \quad (18)$$

where the indices i , j , and k are all different. With the condition $c_{ij} = \delta_{ij}$ (i.e. the delta function) when $\tau = 0$, the application of equations (16) yields the average values:

$$\langle c_{jj}c_{kk} + c_{jk}c_{kj} \rangle = \exp[-(4R_i + R_j + R_k)\tau] \quad (19)$$

The application of equations (16) and (18) in deriving the average values of the c_{ri}^2 yields three first-order linear differential equations that are related because $\sum_i c_{ri}^2 = 1$. The average values are:

$$\langle c_{ii}^2 \rangle = \left(\frac{1}{3}\right) + \left(\frac{1}{6}\right)(2 + \delta_i) \exp(-\tau/\tau_-) + \left(\frac{1}{6}\right)(2 - \delta_i) \exp(-\tau/\tau_+) \quad (20)$$

$$\langle c_{jk}^2 \rangle = \left(\frac{1}{3}\right) - \left(\frac{1}{6}\right)(1 - \delta_i) \exp(-\tau/\tau_-) - \left(\frac{1}{6}\right)(1 + \delta_i) \exp(-\tau/\tau_+) \quad (21)$$

where

$$\delta_i = (R_i - R)/(R^2 - L^2)^{1/2} \quad (22)$$

$$1/\tau_{\pm} = 6[R \pm (R^2 - L^2)^{1/2}] \quad (23)$$

in which

$$R = \left(\frac{1}{3}\right)(R_1 + R_2 + R_3) \quad (24)$$

$$L^2 = \left(\frac{1}{3}\right)(R_1 R_2 + R_1 R_3 + R_2 R_3) \quad (25)$$

The final result, after averaging over all S_0 , is⁷

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle = & \left(\frac{1}{2}\right)K_h \langle C_+ \exp(-|\tau|/\tau_+) + C_- \exp(-|\tau|/\tau_-) \\ & + C_1 \exp(-|\tau|/\tau_1) + C_2 \exp(-|\tau|/\tau_2) \\ & + C_3 \exp(-|\tau|/\tau_3) \rangle_{av} \end{aligned} \quad (26)$$

in which

$$K_0 = \frac{4}{5} \quad (27a)$$

$$K_1 = \frac{2}{1} \quad (27b)$$

$$K_2 = \frac{8}{15} \quad (27c)$$

$$C_B = C_1 + C_2 = 6n'n''(m'm'' + l'l'') \quad (33b)$$

$$1/\tau_1 = 4R_1 + R_2 + R_3 \quad (28a)$$

$$C_C = C_- + C_3 = (\frac{3}{2})(l'^2 - m'^2)(l''^2 - m''^2) + 6l'l''m'm'' \quad (33c)$$

$$1/\tau_2 = 4R_2 + R_1 + R_3 \quad (28b)$$

$$1/\tau_3 = 4R_3 + R_1 + R_2 \quad (28c)$$

The operation $\langle \cdots \rangle_{av}$ on the right-hand side of equations (26) and (31) signifies the final average over molecular internal motions that introduce additional time dependencies into the correlation function. If there are no internal motions and the ellipsoid is rigid, this final averaging procedure is unnecessary. In this case, l'', m'', n'' are equal to l', m', n' , respectively.

The correlation functions for a rigid, completely asymmetric ellipsoid are then

$$C_+ = d - e \quad (29a)$$

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle = & (\frac{1}{2})K_h[C_+ \exp(-|\tau|/\tau_+) + C_- \exp(-|\tau|/\tau_-) \\ & + C_1 \exp(-|\tau|/\tau_1) + C_2 \exp(-|\tau|/\tau_2) \\ & + C_3 \exp(-|\tau|/\tau_3)] \end{aligned} \quad (34)$$

$$C_- = d + e \quad (29b)$$

$$C_1 = 6m'n'm''n'' \quad (29c)$$

It is useful to note that $C_+ + C_- + C_1 + C_2 + C_3 = 2$. For a sphere, $R_1 = R_2 = R_3 = R_s$, where R_s is the rotational diffusion constant for the sphere and all of the correlation times are equal to the well-known result $\tau_c = 1/6R_s$.

Similarly, the correlation functions for a rigid, axially symmetric ellipsoid are

$$C_2 = 6l'n'l''n'' \quad (29d)$$

$$C_3 = 6l'm'l''m'' \quad (29e)$$

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle = & (\frac{1}{2})K_h[C_A \exp(-|\tau|/\tau_A) \\ & + C_B \exp(-|\tau|/\tau_B) + C_C \exp(-|\tau|/\tau_C)] \end{aligned} \quad (35)$$

in which

$$d = (\frac{1}{2})[3(l'^2l''^2 + m'^2m''^2 + n'^2n''^2) - 1] \quad (30a)$$

$$\begin{aligned} e = & (\frac{1}{2})[\delta_1(l'^2l''^2 + m'^2m''^2 + n'^2m''^2) \\ & + \delta_2(m'^2m''^2 + l'^2n''^2 + n'^2l''^2) \\ & + \delta_3(n'^2n''^2 + l'^2m''^2 + m'^2l''^2)] \end{aligned} \quad (30b)$$

In this case, the C_i simplify to:

$$C_A = (\frac{1}{2})(1 - 3n'^2)^2 \quad (36a)$$

$$C_B = 6n'^2(1 - n'^2) \quad (36b)$$

$$C_C = (\frac{3}{2})(1 - n'^2)^2 \quad (36c)$$

Frequently, the shape of a molecule approximates an axially symmetric ellipsoid. In this case, given by $R_1 = R_2$, the correlation function in equation (26) is simplified to

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle = & (\frac{1}{2})K_h[C_A \exp(-|\tau|/\tau_A) \\ & + C_B \exp(-|\tau|/\tau_B) + C_C \exp(-|\tau|/\tau_C)]_{av} \end{aligned} \quad (31)$$

where

$$1/\tau_A = 6R_2 \quad (32a)$$

$$1/\tau_B = 5R_2 + R_3 \quad (32b)$$

$$1/\tau_C = 2R_2 + 4R_3 \quad (32c)$$

$$C_A = C_+ = (\frac{1}{2})(1 - 3n'^2)(1 - 3n''^2) \quad (33a)$$

Note that the correlation functions are independent of l' and m' . The $J_h(\omega)$ depend only on the angle between the nuclear interaction vector and the motional symmetry axis.

The rotational correlation function is a sum of five (or three) simple exponential decay functions. This functional form is a consequence of the assumption of rotational diffusion that involves only infinitesimally small rotational steps.

4 CORRELATION FUNCTIONS FOR AXIALLY SYMMETRIC ELLIPSOIDS WITH INTERNAL MOTION

When the nuclear interaction vector reorients independently inside the ellipsoid, the direction cosines l' , m' , and n' of the interaction vector with respect to the rectangular coordinate system S' of the ellipsoid are time dependent and time dependent averaging on the right-hand side of equation (31)

must be performed to obtain the correlation functions. Because the internal rotational motion is independent of the rotational motions of the ellipsoid, we must evaluate the separate correlation functions (i.e. the C_i) in equation (33). To do this, it is convenient to express the internal motion in terms of spherical polar coordinates in S' . The relaxation vector rotates about the z' axis with a constant polar angle Δ and a time dependent azimuthal angle $\phi'(t)$. In the case of a methyl group, the z' axis is the threefold symmetry axis. The z' axis makes a constant angle α with the Z' symmetry axis of the ellipsoid. In the coordinate system of the ellipsoid,

$$C_A = \left(\frac{1}{2}\right)[1 - 3 \cos^2 \theta(t)][1 - 3 \cos^2 \theta(t + \tau)] \quad (37a)$$

$$C_B = \left(\frac{3}{2}\right)\langle \sin 2\theta(t) \exp[i\phi(t)] \sin 2\theta(t + \tau) \times \exp[-i\phi(t + \tau)] \rangle \quad (37b)$$

$$C_C = \left(\frac{3}{2}\right)\langle \sin^2 \theta(t) \exp[2i\phi(t)] \sin^2 \theta(t + \tau) \times \exp[-2i\phi(t + \tau)] \rangle \quad (37c)$$

where $\theta(t)$ and $\phi(t)$ are the time dependent polar and azimuthal angles of the interaction vector in S' .

The quantities in brackets are products of spherical harmonics; the C_i can be expressed in terms of the constant angles α and Δ and of the time dependent angle $\phi'(t)$ by using the transformation formulas for spherical harmonics. The result of setting $\phi''(\tau) = \phi'(t + \tau) - \phi'(t)$ and averaging over the random distribution at time t is⁸

$$C_A = C_{A1} + C_{A2}\langle \cos \phi''(\tau) \rangle + C_{A3}\langle \cos 2\phi''(\tau) \rangle \quad (38a)$$

$$C_{A1} = \left(\frac{1}{8}\right)(1 - 3 \cos^2 \alpha)^2(1 - 3 \cos^2 \Delta)^2 \quad (38b)$$

$$C_{A2} = \left(\frac{9}{16}\right) \sin^2 2\alpha \sin^2 2\Delta \quad (38c)$$

$$C_{A3} = \left(\frac{9}{16}\right) \sin^4 \Delta \sin^4 \alpha \quad (38d)$$

$$C_B = C_{B1} + C_{B2}\langle \cos \phi''(\tau) \rangle + C_{B3}\langle \cos 2\phi''(\tau) \rangle \quad (39a)$$

$$C_{B1} = \left(\frac{3}{8}\right) \sin^2 2\alpha (3 \cos^2 \Delta - 1)^2 \quad (39b)$$

$$C_{B2} = \left(\frac{3}{4}\right)(\cos^2 2\alpha + \cos^2 \alpha) \sin^2 2\Delta \quad (39c)$$

$$C_{B3} = \left(\frac{3}{4}\right)[\sin^2 \alpha + \left(\frac{1}{4}\right) \sin^2 2\alpha] \sin^4 \Delta \quad (39d)$$

$$C_C = C_{C1} + C_{C2}\langle \cos \phi''(\tau) \rangle + C_{C3}\langle \cos 2\phi''(\tau) \rangle \quad (40a)$$

$$C_{C1} = \left(\frac{3}{8}\right) \sin^4 \alpha (3 \cos^2 \Delta - 1)^2 \quad (40b)$$

$$C_{C2} = \left(\frac{3}{4}\right)[\sin^2 \alpha + \left(\frac{1}{4}\right) \sin^2 2\alpha] \sin^2 2\Delta \quad (40c)$$

$$C_{C3} = \left(\frac{3}{16}\right)[(1 + \cos^2 \alpha)^2 + 4 \cos^2 \alpha] \sin^4 \Delta \quad (40d)$$

Each of the three coefficients C_A , C_B , and C_C consists of a time-independent term (subscripted 1) and two terms that are time dependent because of the internal motion.

The internal motion determines the time dependence of $\phi''(\tau)$. One model for the time dependence is that of a terminal methyl group in an n -paraffin molecule in the s -*trans* configuration. Because there are three equivalent positions of the methyl group, the allowed values of $\phi''(\tau)$ are 0° , 120° , and 240° . Here, the internal motion occurs by random jumping of the methyl group from any of these equivalent positions to either of the two adjacent positions at an average rate of $(3\tau_{ci})^{-1}$. With this type of motion,⁹ we have

$$\langle \cos \phi''(\tau) \rangle = \langle \cos 2\phi''(\tau) \rangle = \exp(-|\tau|/\tau_{ci}) \quad (41)$$

so that

$$C_A = C_{A1} + (C_{A2} + C_{A3}) \exp(-|\tau|/\tau_{ci}) \quad (42a)$$

$$C_B = C_{B1} + (C_{B2} + C_{B3}) \exp(-|\tau|/\tau_{ci}) \quad (42b)$$

$$C_C = C_{C1} + (C_{C2} + C_{C3}) \exp(-|\tau|/\tau_{ci}) \quad (42c)$$

As a result of this type of internal motion, the correlation function contains the three additional correlation times

$$1/\tau_{A23} = 6R_2 + 1/\tau_{ci} \quad (43a)$$

$$1/\tau_{B23} = 5R_2 + R_3 + 1/\tau_{ci} \quad (43b)$$

$$1/\tau_{C23} = 2R_2 + 4R_3 + 1/\tau_{ci} \quad (43c)$$

Another model of internal motion is a stochastic diffusion process among a very large number of equilibrium positions that are uniformly distributed from $\phi' = 0$ to 2π such that $\langle \phi''^2 \rangle = 2R_i\tau$, where R_i is the internal rotational diffusion coefficient. With this model⁹ of internal motion,

$$\langle \cos \phi''(\tau) \rangle = \exp(-R_i|\tau|) \quad (44a)$$

$$\langle \cos 2\phi''(\tau) \rangle = \exp(-4R_i|\tau|) \quad (44b)$$

so that

$$C_A = C_{A1} + C_{A2} \exp(-R_i|\tau|) + C_{A3} \exp(-4R_i|\tau|) \quad (45a)$$

$$C_B = C_{B1} + C_{B2} \exp(-R_i|\tau|) + C_{B3} \exp(-4R_i|\tau|) \quad (45b)$$

$$C_C = C_{C1} + C_{C2} \exp(-R_i|\tau|) + C_{C3} \exp(-4R_i|\tau|) \quad (45c)$$

giving the six new correlation times

$$1/\tau_{A2} = 6R_2 + R_i \quad (46a)$$

$$1/\tau_{A3} = 6R_2 + 4R_i \quad (46b)$$

$$1/\tau_{B2} = 5R_2 + R_3 + R_i \quad (46c)$$

$$1/\tau_{B3} = 5R_2 + R_3 + 4R_i \quad (46d)$$

$$1/\tau_{C2} = 2R_2 + 4R_3 + R_i \quad (46e)$$

$$1/\tau_{C3} = 2R_2 + 4R_3 + 4R_i \quad (46f)$$

Frequently, the internal rotation axis lies along the symmetry axis of the ellipsoid so that $\alpha = 0$ in equations (38)–(40). Consequently, the value of many of these equations is zero and the correlation function is⁷

$$\langle F_h(t)F_h^*(t + \tau) \rangle = \left(\frac{1}{2}\right)K_h[A \exp(-|\tau|/\tau'_A) + B \exp(-|\tau|/\tau'_B) + C \exp(-|\tau|/\tau'_C)] \quad (47)$$

in which

$$A = \left(\frac{1}{2}\right)(1 - 3 \cos^2 \Delta)^2 \quad (48a)$$

$$B = \left(\frac{3}{2}\right) \sin^2 2\Delta \quad (48b)$$

$$C = \left(\frac{3}{2}\right) \sin^4 \Delta \quad (48c)$$

For the internal jump model,

$$1/\tau'_A = 1/\tau_A = 6R_2 \quad (49a)$$

$$1/\tau'_B = 5R_2 + R_3 + \tau_{ci} \quad (49b)$$

$$1/\tau'_C = 2R_2 + 4R_3 + \tau_{ci} \quad (49c)$$

For the internal rotational diffusion model,

$$1/\tau'_A = 1/\tau_A = 6R_2 \quad (50a)$$

$$1/\tau'_B = 5R_2 + R_3 + R_i \quad (50b)$$

$$1/\tau'_C = 2R_2 + 4R_3 + 4R_i \quad (50c)$$

Generally, the correlation function of a nonspherical molecule that reorients at different rates about different molecular axes depends on many external and internal molecular motions. We can use NMR relaxation time measurements on nuclei that have different nuclear interaction vector orientations in the molecule to give information on the internal and external molecular motions.

5 CORRELATION FUNCTIONS FOR INTERGROUP MAGNETIC DIPOLAR RELAXATION WITH INTERNAL MOTION

In intramolecular magnetic dipolar relaxation between a nucleus of a rotating group and a nucleus on the remainder of the molecule, the length as well as the orientation of the nuclear interaction vector is time dependent. Consequently, we use the $F_h(t)$ as defined in equation (4). To restrict the calculation of the correlation function to simple but useful cases, we assume the following geometry.¹⁰ The two nuclei rotate in parallel planes about the same perpendicular axis. The planes are separated by the distance b and the radii of rotation are a and c . This geometry describes the magnetic dipolar interaction between protons in different methyl groups in ethane, protons on neighboring carbon atoms in *n*-paraffins, methyl and ring protons in toluene, fluorine nuclei and protons in benzotrifluoride, etc.

Let us assume that the molecule is an axially symmetric ellipsoid and that the internal rotation axis is parallel to the ellipsoid symmetry axis. Because the internal motion causes simultaneous changes in the orientation and length of the internuclear vector, the correlation function is an extension of equations (31)–(33) to include a time dependent r .

$$\langle F_h(t)F_h^*(t + \tau) \rangle = \left(\frac{1}{2}\right)K_h \langle C_{Ar} \exp(-|\tau|/\tau_A) + C_{Br}(-|\tau|/\tau_B) + C_{Cr} \exp(-|\tau|/\tau_C) \rangle_{av} \quad (51)$$

where

$$1/\tau_A = 6R_2 \quad (52a)$$

$$1/\tau_B = 5R_2 + R_3 \quad (52b)$$

$$1/\tau_C = 2R_2 + 4R_3 \quad (52c)$$

$$C_{Ar} = \left(\frac{1}{2}\right)(1 - 3n'^2)(1 - 3n''^2)r'^{-3}r''^{-3} \quad (53a)$$

$$C_{Br} = 6n'n''(m'm'' + l'l'')r'^{-3}r''^{-3} \quad (53b)$$

$$C_{Cr} = \left[\left(\frac{3}{2}\right)(l'^2 - m'^2)(l''^2 - m''^2) + 6l'l''m'm''\right]r'^{-3}r''^{-3} \quad (53c)$$

The operation $\langle \dots \rangle_{av}$ on the right-hand side of equation (51) signifies the final average over the internal motions. These motions are statistically independent from the rotational motions of the ellipsoid. The values at time t are l' , m' , n' , and r' , and those at the later time $t + \tau$ are l'' , m'' , n'' , and r'' .

r'' . In terms of the geometry of the problem, the C quantities are:

$$C_{Ar} = \left(\frac{1}{2}\right)r'^{-5}r''^{-5}\{(a^2 + c^2 - 2b^2)^2 - 2(a^3c + ac^3 - 2ab^2c) \\ \times [\cos(\phi'_1 - \phi'_2) + \cos(\phi''_1 - \phi''_2)] \\ + 4a^2c^2 \cos(\phi'_1 - \phi'_2) \cos(\phi''_1 - \phi''_2)\} \quad (54a)$$

$$C_{Br} = 6r'^{-5}r''^{-5}b^2\{c^2 \cos(\phi'_1 - \phi''_1) + a^2 \cos(\phi'_2 - \phi''_2) \\ - ac[\cos(\phi'_1 - \phi''_2) + \cos(\phi'_2 - \phi''_1)]\} \quad (54b)$$

$$C_{Cr} = \left(\frac{3}{2}\right)r'^{-5}r''^{-5}\{c^4 \cos(2\phi'_1 - 2\phi''_1) + a^4 \cos(2\phi'_2 - 2\phi''_2) \\ + 4a^2c^2 \cos(\phi'_1 + \phi'_2 - \phi''_1 - \phi''_2) \\ + a^2c^2[\cos(2\phi'_1 - 2\phi''_2) + \cos(2\phi'_2 - 2\phi''_1)] \\ - 2ac^3[\cos(2\phi'_1 - \phi''_1 - \phi''_2) + \cos(\phi'_1 + \phi'_2 - 2\phi''_1)] \\ - 2a^3c[\cos(2\phi'_2 - \phi''_1 - \phi''_2) + \cos(\phi'_1 + \phi'_2 - 2\phi''_2)]\} \quad (54c)$$

in which ϕ'_1 and ϕ'_2 are the azimuthal angles of the nuclei at time t and ϕ''_1 and ϕ''_2 are the angles at time $t + \tau$.

Calculating the time dependent average values $\langle C_{ir} \rangle$ involves integrals of functions that approach the complete elliptic integrals at long τ values if $(\phi'_1 - \phi''_1)$ and $(\phi'_2 - \phi''_2)$ are allowed to have all values from 0 to 2π . The calculation is greatly simplified with the model in which one nucleus occupies three positions 120° apart and the other nucleus occupies three similar positions that are staggered with respect to those of the former nucleus. Here, there are only two different values of r , as given by the expressions:

$$r_1^2 = a^2 + b^2 + c^2 + 2ac \quad (55a)$$

$$r_s^2 = a^2 + b^2 + c^2 - ac \quad (55b)$$

If each nucleus independently and randomly jumps among its three positions, the $\langle C_{ir} \rangle$ are

$$\langle C_{Ar} \rangle = C_{a1} + C_{a2} \exp[-|\tau|(1/\tau_1 + 1/\tau_2)] \quad (56a)$$

$$\langle C_{Br} \rangle = C_{b1} \exp[-|\tau|/\tau_1] + C_{b2} \exp[-|\tau|/\tau_2] \\ + C_{b3} \exp[-|\tau|(1/\tau_1 + 1/\tau_2)] \quad (56b)$$

$$\langle C_{Cr} \rangle = C_{c1} \exp[-|\tau|/\tau_1] + C_{c2} \exp[-|\tau|/\tau_2] \\ + C_{c3} \exp[-|\tau|(1/\tau_1 + 1/\tau_2)] \quad (56c)$$

where

$$C_{a1} = \left(\frac{1}{18}\right)[(a^2 + c^2 - 2b^2)^2 Q_1 + 4a^2c^2 Q_2 \\ - 4(a^3c + ac^3 - 2ab^2c) Q_3] \quad (57a)$$

$$C_{a2} = \left(\frac{1}{9}\right)[(a^2 + c^2 - 2b^2)^2 Q_2 + a^2c^2 Q_5 \\ - 2(a^3c + ac^3 - 2ab^2c) Q_4] \quad (57b)$$

$$C_{b1} = \left(\frac{2}{3}\right)b^2(c^2 Q_1 + a^2 Q_2 - 2ac Q_3) \quad (57c)$$

$$C_{b2} = \left(\frac{2}{3}\right)b^2(c^2 Q_2 + a^2 Q_1 - 2ac Q_3) \quad (57d)$$

$$C_{b3} = \left(\frac{2}{3}\right)b^2(a + c)^2 Q_2 \quad (57e)$$

$$C_{c1} = \left(\frac{1}{6}\right)(c^4 Q_1 + a^4 Q_2 + 6a^2c^2 Q_6 - 4ac^3 Q_3 + 4a^3c Q_2) \quad (57f)$$

$$C_{c2} = \left(\frac{1}{6}\right)(c^4 Q_2 + a^4 Q_1 + 6a^2c^2 Q_6 + 4ac^3 Q_2 - 4a^3c Q_3) \quad (57g)$$

$$C_{c3} = \left(\frac{1}{6}\right)(c^4 Q_2 + a^4 Q_2 + 6a^2c^2 Q_7 - 4ac^3 Q_3 - 4a^3c Q_3) \quad (57h)$$

in which

$$Q_1 = 4r_s^{-10} + r_1^{-10} + 4r_s^{-5}r_1^{-5} \quad (58a)$$

$$Q_2 = r_s^{-10} + r_1^{-10} - 2r_s^{-5}r_1^{-5} \quad (58b)$$

$$Q_3 = 2r_s^{-10} - r_1^{-10} - r_s^{-5}r_1^{-5} \quad (58c)$$

$$Q_4 = r_s^{-10} - 2r_1^{-10} + r_s^{-5}r_1^{-5} \quad (58d)$$

$$Q_5 = r_s^{-10} + 4r_1^{-10} + 4r_s^{-5}r_1^{-5} \quad (58e)$$

$$Q_6 = r_1^{-10} - r_s^{-5}r_1^{-5} \quad (58f)$$

$$Q_7 = 3r_s^{-10} + r_1^{-10} + 2r_s^{-5}r_1^{-5} \quad (58g)$$

The correlation time of internal motion of the nucleus associated with ϕ_1 and c is τ_1 and that of the nucleus associated with ϕ_2 and a is τ_2 .

The final correlation times are given by:

$$1/\tau_{a1} = 1/\tau_A = 6R_2 \quad (59a)$$

$$1/\tau_{a2} = 6R_2 + 1/\tau_1 + 1/\tau_2 \quad (59b)$$

$$1/\tau_{b1} = 5R_2 + R_3 + 1/\tau_1 \quad (59c)$$

$$1/\tau_{b2} = 5R_2 + R_3 + 1/\tau_2 \quad (59d)$$

$$1/\tau_{b3} = 5R_2 + R_3 + 1/\tau_1 + 1/\tau_2 \quad (59e)$$

$$1/\tau_{c1} = 2R_2 + 4R_3 + 1/\tau_1 \quad (59f)$$

$$1/\tau_{c2} = 2R_2 + 4R_3 + 1/\tau_2 \quad (59g)$$

$$1/\tau_{c3} = 2R_2 + 4R_3 + 1/\tau_1 + 1/\tau_2 \quad (59h)$$

Use of this simple model of internal motion with magnetic dipolar relaxation interaction increases the number of correlation times for the axially symmetric ellipsoid from three to eight. If the internal rotational axis were not parallel to the ellipsoid symmetry axis, then more than eight correlation times would result. Even in this simple case, many simplifications occur if the molecule rotates with spherical symmetry, if $\tau_1 = \tau_2$, or if either of the two nuclei does not rotate internally.

Examination of the sum of the eight coefficients given by equation (57) reveals insight into the effects of internal motion. This sum is $(4/3)r_s^{-6} + (2/3)r_l^{-6}$, which is twice the weighted average of r^{-6} . The corresponding sum for a rigid molecule, obtained from the sum of equation (53) when the single-primed and double primed quantities are equal, is $2r^{-6}$. The effect of the internal motion, then, is to split r^{-6} into several terms. Most of these terms have shorter correlation times than for a rigid molecule. One of the terms is independent of the internal motion and it gives rise to the ‘order parameter’ that represents a kind of order in a large, flexible molecule.

6 ‘MODEL-FREE’ CORRELATION FUNCTIONS FOR FLEXIBLE MACROMOLECULES

Modern applications of NMR include the use of relaxation time measurements to investigate the dynamics of flexible macromolecules, such as polymers, lipids, and proteins (see *Protein Dynamics from NMR Relaxation*), in solution. Clearly, the correlation function for such systems is extremely complex because many different correlation times and associated preexponential factors are involved in its formulation. In addition, we must assume structural and dynamical models to make the formulation. Even with such a formulation, the typical NMR relaxation time measurement does not allow for the experimental evaluation of all the parameters that are in the assumed models.

We can use the expressions presented in this article with various assumed dynamics and structures to formulate the correlation functions for a complex flexible molecule and compute values of relaxation times. We can use these values to validate simplified expressions for the spectral density to figure out (a) what is the unique information in a set of relaxation time data and (b) how can we extract this information from the data?

Such simplified expressions are called^{11–13} ‘model-free’ because the analysis of relaxation time data using these

expressions does not require the adoption of a physical model. However, the derivation and productive use of these expressions do require the assumption of certain limiting cases. The description of the motion of the flexible macromolecule is that of overall reorientation of the molecular framework and internal motions within this framework that are independent of the reorientation of the framework. To illustrate this approach, we factor equation (47) as

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle &= \left(\frac{1}{2}\right)K_h[\exp(-|\tau|/\tau_{ov})] \\ &\quad \times [A + B \exp(-|\tau|/\tau_{i1}) + C \exp(-|\tau|/\tau_{i2})] \end{aligned} \quad (60)$$

in which $A + B + C = 2$. When the internal motion is rotational diffusion, for example, the correlation times are:

$$1/\tau_{ov} = 1/\tau_A = 6R_2 \quad (61a)$$

$$1/\tau_{i1} = -R_2 + R_3 + R_i \quad (61b)$$

$$1/\tau_{i2} = -4R_2 + 4R_3 + 4R_i \quad (61c)$$

We can view equation (60) as the product of a correlation function $C_{ov}(\tau)$ that depends only on overall motion, and a correlation function $C_{in}(\tau)$ that contains a constant term and terms that involve the internal motion, so that

$$\langle F_h(t)F_h^*(t+\tau) \rangle = K_h C_{ov}(\tau) C_{in}(\tau) \quad (62)$$

where

$$C_{ov}(\tau) = \exp(-|\tau|/\tau_{ov}) \quad (63a)$$

$$C_{in}(\tau) = \left(\frac{1}{2}\right)[A + B \exp(-|\tau|/\tau_{i1}) + C \exp(-|\tau|/\tau_{i2})] \quad (63b)$$

The model-free approach is to approximate $C_{in}(\tau)$ as

$$C_{in}(\tau) = \zeta^2 + (1 - \zeta^2) \exp(-|\tau|/\tau_{eff}) \quad (64)$$

where ζ is called an order parameter, equal to $(A/2)^{1/2}$ in the present example, and τ_{eff} is an effective correlation time as given by the definition:

$$\tau_{eff} = (1 - \zeta^2)^{-1} \int_0^\infty [C_{in}(\tau) - \zeta^2] d\tau \quad (65)$$

When the internal motions are rapid so that $2\omega_0/R_i \ll 1$, use of this definition in the spectral density function provides an excellent approximation.

In considering the consequences of the fluctuations of internuclear separation on magnetic dipolar relaxation that are

caused by the internal motion, we can use equations (56)–(59) to factor equation (51) as

$$\begin{aligned} \langle F_h(t) F_h^*(t + \tau) \rangle &= \left(\frac{1}{2}\right) K_h [\exp(-|\tau|/\tau_{ov})] \\ &\times [C_{a1} + C_{a2} \exp(-|\tau|/\tau_{i1}) \\ &+ C_{b1} \exp(-|\tau|/\tau_{i2}) + C_{b2} \exp(-|\tau|/\tau_{i3}) \\ &+ C_{b3} \exp(-|\tau|/\tau_{i4}) + C_{c1} \exp(-|\tau|/\tau_{i5}) \\ &+ C_{c2} \exp(-|\tau|/\tau_{i6}) + C_{c3} \exp(-|\tau|/\tau_{i7})] \end{aligned} \quad (66)$$

in which

$$1/\tau_{ov} = 6R_2 \quad (67a)$$

$$1/\tau_{i1} = 1/\tau_1 + 1/\tau_2 \quad (67b)$$

$$1/\tau_{i2} = -R_2 + R_3 + 1/\tau_1 \quad (67c)$$

$$1/\tau_{i3} = -R_2 + R_3 + 1/\tau_2 \quad (67d)$$

$$1/\tau_{i4} = -R_2 + R_3 + 1/\tau_1 + 1/\tau_2 \quad (67e)$$

$$1/\tau_{i5} = -4R_2 + 4R_3 + 1/\tau_1 \quad (67f)$$

$$1/\tau_{i6} = -4R_2 + 4R_3 + 1/\tau_2 \quad (67g)$$

$$1/\tau_{i7} = -4R_2 + 4R_3 + 1/\tau_1 + 1/\tau_2 \quad (67h)$$

The analogous order parameter ζ_r for internal motion with equation (62) is similarly defined by:

$$C_{in}(\tau) = \zeta_r^2 + (1 - \zeta_r^2) \exp(-|\tau|/\tau_{er}) \quad (68)$$

in which ζ_r is equal to $(C_{a1}/2)^{1/2}$ and τ_{er} is the effective correlation time that is defined in the same fashion as τ_{eff} .

When the internal motions are rapid compared with the overall molecular reorientation rate and obey the condition $2\omega_0/R_i \ll 1$, the correlation function is the sum of two terms. One of these terms involves the overall correlation time and the other term involves the effective correlation time that depends on the internal motions. The term that is dependent on the overall molecular motion is weighted by the order parameter.

7 CORRELATION FUNCTIONS FOR INTERMOLECULAR MAGNETIC DIPOLAR RELAXATION

Magnetic dipolar NMR relaxation between nuclei of different molecules is an important relaxation mechanism that depends on Brownian motion. The values of r , θ , and ϕ are time dependent because of translational diffusion of the molecular centers and rotation of the molecules about their centers. If the interacting nuclei are at the centers of spherical molecules, the correlation functions can be calculated¹ from classical diffusion theory. The correlation function is¹

$$\begin{aligned} \langle F_h(t) F_h^*(t + \tau) \rangle &= \frac{\alpha_h N}{d^3} \\ &\times \int_0^\infty [J_{3/2}(u)]^2 \exp\left[-\left(\frac{2D}{d^2} u^2 \tau\right)\right] \frac{du}{u} \end{aligned} \quad (69)$$

where N is the number of nuclear spins per cm^3 , D is the translational diffusion coefficient, d is the minimum distance of approach between nuclei on different molecules, $J_{3/2}$ is a Bessel function, α_h is a numerical factor that depends on h , and u is a dummy integration parameter. The spectral energy densities are then

$$J_h(\omega) = \frac{\alpha_h N}{dD} \int_0^\infty [J_{3/2}(u)]^2 \frac{u du}{u^4 + \omega^2 \tau^2} \quad (70)$$

where $\tau = d^2/2D$. The effects on $J_h(\omega)$ in the case of off-center nuclei¹⁴ depend on the ratio τ/τ_c and they are not insignificant.

8 EXPERIMENTAL AND THEORETICAL CORRELATION TIMES OF RIGID MOLECULES

8.1 Evaluation of Correlation Times from NMR Relaxation Data

We can express the correlation functions in the preceding sections of this article (except for Section 7) as the following sum of exponential functions:

$$\langle F_h(t) F_h^*(t + \tau) \rangle = \left(\frac{1}{2}\right) \langle F_h(t) F_h^*(t) \rangle \sum_j C_j \exp(-|\tau|/\tau_{cj}) \quad (71)$$

in which $\sum_j C_j = 2$. The values of the correlation times τ_{cj} depend on the rates of molecular motions, and the number and values of the C_j depend on the details of molecular structure and motion. Because equation (71) is a sum of exponential functions, the spectral densities $J_h(\omega)$ in equation (3) are given by the sum of Lorentzian functions

$$J_h(\omega) = \langle F_h(t) F_h^*(t) \rangle \sum_j C_j [\tau_{cj}/(1 + \omega^2 \tau_{cj}^2)] \quad (72)$$

Note that the spectral densities for intermolecular magnetic dipolar relaxation in Section 7 are not sums of Lorentzian functions because equation (69) is not a sum of exponential functions.

The models presented in the preceding sections do not explicitly include various motions, such as high frequency, small amplitude bond stretching vibrations, as well as torsional oscillations about temporary equilibrium positions that change because of Brownian motion. The inclusion of such motions would increase the number of terms in equations (71) and (72) and could decrease the spectral density. If the decrease in spectral density is significant, the application of the preceding models to relaxation time data could lead to inconsistencies of interpretation. In the case of magnetic dipolar relaxation of CH_3 groups, the predicted decrease due to torsional oscillations agrees¹⁵ with experiment.

The study of Brownian motions by means of NMR relaxation time measurements involves the evaluation of the τ_{cj} from $J_h(\omega)$ values that are obtained from the measured relaxation times. These relaxation times should be from different nuclei that have different orientations of relaxation interaction vector with respect to the various axes of the ellipsoidal molecule.

There can be an ambiguity in evaluating correlation times from relaxation data, especially for large molecules with relatively small R_i values. Because the function $\tau_{cj}/(1 + \omega^2\tau_{cj}^2)$ is at its maximum value $1/\omega$ at $\omega\tau_{cj} = 1$, there is an ambiguity of τ_{cj} values when the 'experimental' value of $\tau_{cj}/(1 + \omega^2\tau_{cj}^2)$ is less than $1/\omega$. This ambiguity does not occur if, for example, all of the τ_{cj} values are small compared to $1/\omega$. In ordinary NMR spectrometers, this condition is met for nonviscous liquids. For example, $2\omega_0\tau_c \approx 0.05$ for protons in liquid water at 0 °C in a 750 MHz NMR spectrometer. Clearly, the simplest circumstance is a rigid, spherical molecule of a nonviscous liquid so that there is only one correlation time. We can compare the correlation time obtained from the analysis of the NMR relaxation time to the value that is predicted from liquid properties and molecular parameters.

8.2 Relationship of Rotational Correlation Times to Brownian Motion

In the preceding sections of this article, the correlation functions for a rigid ellipsoid are expressed in terms of the rotational diffusion coefficients R_i . The R_i values can be determined from the analysis of the proper relaxation time measurements. The next step is to relate the R_i to Brownian motion in the liquid. Molecules in the liquid undergo random collisions with other molecules. Perrin's exquisitely detailed description of the translational and rotational motion of an ellipsoid that is immersed in a liquid and experiencing collisions with the liquid molecules⁵ is useful in establishing this relationship.

It is assumed that the average action of molecular collisions on the ellipsoid gives rise to the friction of viscosity. Fluctuations of these collisions produce impulses of torque that affect the rotation of the ellipsoid. These impulses couple the rotational kinetic energy of the ellipsoid to the kinetic energy of its surroundings so that thermodynamic equilibrium obtains and the average kinetic energy for each degree of freedom is

equal to $kT/2$, where T is the absolute temperature of the fluid and k is Boltzmann's constant.

Let ω_1, ω_2 , and ω_3 be the angular velocities of the ellipsoid about the X, Y , and Z axes and I_1, I_2 and I_3 be the moments of inertia about these axes, respectively. Similarly, let α_1, α_2 , and α_3 be small rotation angles about these axes. In the following discussion, designate the subscripts 1, 2, and 3 as the subscript i . If K is the kinetic energy of the particle, the angular momenta λ_i are the partial derivatives of K with respect to the angular velocities ω_i :

$$\lambda_i = \partial K / \partial \omega_i \quad (73)$$

At each instant, the collisions with the surrounding molecules produce a torque L_i about the respective ellipsoid axes. Each L_i is the sum of the frictional torque $-C_i\omega_i$ that results from viscosity and a variable torque Γ_i that is caused by fluctuations of the collisions. This torque causes changes in angular momenta as given by

$$d\lambda_i/dt = -C_i\omega_i + \Gamma_i \quad (74)$$

We take time intervals Δt that are sufficiently great so that there is almost complete statistical independence of the angular displacements that are produced by torque Γ_i during two consecutive time intervals, and nevertheless, sufficiently small so that the rotation during each interval is very small. If α_i are the very small angles that are needed to describe the changes in orientation from its initial position to its orientation at the end of time interval Δt , to a first approximation the angular velocities are

$$\omega_i = d\alpha_i/dt \quad (75)$$

Under these conditions, the angular displacements that result from successive impulses due to the thermal motions of the liquid are independent and simply additive. If we divide the time interval Δt into very small successive intervals δt , the variable couple Γ_i communicates to the ellipsoid an impulse $\mathcal{L}_i$ that is the integral of Γ_i over the interval δt ,

$$\mathcal{L}_i = \int_0^{\delta t} \Gamma_i dt \quad (76)$$

Also, to calculate the net angular displacement that results from these impulses, it suffices to calculate the displacement that results from each impulse, assuming action on the initially immobile particle, and take the sum of these small displacements as if they are not superposed in time.

Because $\omega_i = d\alpha_i/dt$ and $d\lambda_i/dt = -C_i\omega_i + \Gamma_i$

$$d\lambda_i/dt = -C_i(d\alpha_i/dt) + \Gamma_i \quad (77)$$

Integration between the initial time t_0 and the final time t gives:

$$\lambda_i - \lambda_{i0} = -C_i(\alpha_i - \alpha_{i0}) + \int_{t_0}^t \Gamma_i dt \quad (78)$$

The ellipsoid is assumed to be immobile at time t_0 so that $\lambda_0 = 0$. If the torque Γ_i acts on the particle only during the time interval δt ,

$$\lambda_i = -C_i(\alpha_i - \alpha_{i0}) + \mathcal{L}_i \quad (79)$$

If t is large enough so that the particle is now practically stopped due to the friction, the rotational displacement of the particle that results from the total of the angular impulses $\mathcal{L}$ is

$$\delta\alpha_i = \mathcal{L}_i/C_i \quad (80)$$

The displacement does not depend on the moments of inertia, I_i ; it depends only on the coefficients of friction C_i . However, this result is true only if the preceding approximations are justified by the smallness of the angular displacements.

If the time interval Δt is sufficiently great, the displacement is that which results from the n successive intervals δt that compose it. If the intervals δt are not too small, the successive corresponding impulses are nearly statistically independent, and the net angular displacement $\Delta\alpha_i$ over time Δt is given by:

$$\langle \Delta\alpha_i^2 \rangle = (1/C_i^2) \sum_k \langle \mathcal{L}_{ik}^2 \rangle = n \langle \mathcal{L}_i^2 \rangle / C_i^2 \quad (81)$$

because the average values for time intervals of the same duration δt are equal. Also, the average values of cross terms $\Delta\alpha_i \Delta\alpha_j$ are zero.

The average values of the $\Delta\alpha_i^2$ quantities can be found by noting that the impulses received by the particle maintain statistically a state of agitation that corresponds to the average kinetic energy that, from the equipartition theorem of statistical mechanics, is given by:

$$\langle \lambda_i \omega_i \rangle = kT \quad (82)$$

If the time interval δt is sufficiently small so that the rotational velocity ω_i is nearly constant, integration of equation (74) over δt gives:

$$\lambda_i' = \lambda_i - C_i \omega_i \delta t + \mathcal{L}_i \quad (83)$$

where λ_i and λ_i' are angular momenta at the beginning and end of the interval δt . After squaring and taking the average,

$$\begin{aligned} \langle \lambda_i'^2 \rangle = & \langle \lambda_i^2 \rangle + C_i^2 \langle \omega_i^2 \rangle \delta t^2 + \langle \mathcal{L}_i^2 \rangle \\ & - 2C_i \langle \lambda_i \omega_i \rangle \delta t + 2\langle \lambda_i \mathcal{L}_i \rangle - 2C_i \langle \omega_i \mathcal{L}_i \rangle \delta t \end{aligned} \quad (84)$$

Several characteristics allow us to simplify this expression. Since the system is in steady-state conditions, $\langle \lambda_i'^2 \rangle = \langle \lambda_i^2 \rangle$. The impulses $\mathcal{L}_i$ do not depend directly on the angular velocities, and the intervals δt are assumed to be sufficiently long in order than the impulses may be independent of the previous impulses that have influenced the angular velocities. Therefore, the average values of products of impulses and angular velocities and of products of impulses and angular momenta are null. Finally, the terms in δt^2 are negligible. Equation (84) then reduces to:

$$\langle \mathcal{L}_i^2 \rangle = 2C_i \langle \lambda_i \omega_i \rangle \delta t \quad (85)$$

and use of equation (82) gives the relation:

$$\langle \mathcal{L}_i^2 \rangle = 2C_i kT \delta t \quad (86)$$

Then, because $n\delta t = \Delta t$ equation (81) gives:

$$\langle \Delta\alpha_i^2 \rangle = 2(kT/C_i) \Delta t \quad (87)$$

and $\Delta\alpha_i$ changes with time as described by the rotational diffusion coefficient

$$R_i = kT/C_i \quad (88)$$

In an analogous fashion, Einstein¹⁶ considered the translational Brownian motion of colloidal particles and showed that the translational diffusion coefficient D in an infinitely dilute solution is given by the equation:

$$D = kT/f \quad (89)$$

where f is the frictional coefficient of the particle.

8.3 Relationships between Friction Coefficients and Properties of Molecules and Liquids

8.3.1 Hydrodynamic Models

The strategy to evaluate the C_i and f friction coefficients for *molecules* in ordinary liquids is not completely straightforward. Usually, the results of classical hydrodynamics are used. Stokes¹⁷ considered the special case of the motion of a macroscopic spherical particle of radius a moving with uniform velocity in a continuous fluid (i.e. infinitesimally small particles) of viscosity η . He assumed that the moving sphere carries along with it, *with no slippage*, the layer of fluid in contact with it (i.e. the surface of the sphere is 'wetted' by the fluid medium). Parenthetically, using this assumption avoids the problems of evaluating the friction coefficient between two different materials, the surface of the smooth sphere and the adjacent surface of the fluid medium. Using classical hydrodynamical principles, such as perfect streamline flow, etc., he showed that the translational movement of the sphere is impeded by the sum of two forces: (1) the force ($=4\pi\eta a$) due to pressure built up in front of it, and (2) a frictional force ($=2\pi\eta a$) parallel to its surface. Then, the friction coefficient f_0 is given by

$$f_0 = 6\pi\eta a \quad (90)$$

Einstein¹⁶ noted that *if* one can assume that this equation applies to spherical *molecules* of radius a , the resulting value of the molecular diffusion coefficient is given by the equation

$$D = kT/6\pi\eta a \quad (91)$$

which is known as the Stokes–Einstein equation. This relationship has been experimentally verified many times for particles whose size can be measured directly, including latex particles of only 1300 Å radius in water. The increase in size

due to the monolayer of water molecules is negligible for spheres of such size.

For the case of a sphere rotating uniformly in the continuous medium, the Stokes approach gives the rotational friction coefficient

$$C_i = 8\pi\eta a^3 \quad (92)$$

Following Einstein's lead in assuming that the translational friction coefficient of a molecule obeys the classical hydrodynamic formulation, Debye³ made the analogous assumption that the rotational motion of a spherical molecule is described by rotational diffusion with the classical rotational friction coefficient given above.

Edwardes extended Stokes's calculation of the single rotational friction coefficient of a rotating sphere to evaluate the three friction coefficients for an asymmetric ellipsoid rotating in a continuous fluid. The results, as corrected by Perrin,⁵ are:

$$C_1 = 16\pi\eta(b^2 + c^2)/[3(b^2Q + c^2R)] \quad (93a)$$

$$C_2 = 16\pi\eta(c^2 + a^2)/[3(c^2R + a^2P)] \quad (93b)$$

$$C_3 = 16\pi\eta(a^2 + b^2)/[3(a^2P + b^2Q)] \quad (93c)$$

where a , b , and c are the X' , Y' , and Z' semi-axes of the ellipsoid, and P , Q and R are the elliptic integrals

$$P = \int_0^\infty (a^2 + s)^{-3/2}(b^2 + s)^{-1/2}(c^2 + s)^{-1/2} ds \quad (94a)$$

$$Q = \int_0^\infty (b^2 + s)^{-3/2}(a^2 + s)^{-1/2}(c^2 + s)^{-1/2} ds \quad (94b)$$

$$R = \int_0^\infty (c^2 + s)^{-3/2}(a^2 + s)^{-1/2}(b^2 + s)^{-1/2} ds \quad (94c)$$

These quantities are related by the equations:

$$P + Q + R = 2/(abc) \quad (95)$$

$$a^2P + b^2Q + c^2R = S \quad (96)$$

where

$$S = \int_0^\infty [(a^2 + s)(b^2 + s)(c^2 + s)]^{-1/2} ds \quad (97)$$

For the axially symmetric ellipsoid, with $a = b$ so that $R_1 = R_2$, the C_i simplify to

$$C_1 = C_2 = 32\pi\eta(c^4 - b^4)/\{3[(2c^2 - b^2)S - 2c]\} \quad (98a)$$

$$C_3 = 32\pi\eta b^2(c^2 - b^2)/[3(2c - b^2S)] \quad (98b)$$

Also, for $b > c$,

$$S = 2(b^2 - c^2)^{-1/2} \tan^{-1}[(b^2 - c^2)^{1/2}/c] \quad (99a)$$

and for $b < c$,

$$S = 2(c^2 - b^2)^{-1/2} \ln\{[c + (c^2 - b^2)^{1/2}]/b\} \quad (99b)$$

For a sphere, where $a = b = c$, all the C_i are equal to $8\pi\eta a^3$.

The relationships given above can be used to calculate the NMR correlation times for rigid molecules of a variety of shapes. Generally, for pure liquids and for solutes in solutions in which the solute molecules are not large compared to the solvent molecules, the calculated correlation times are approximately an order of magnitude greater than the values obtained from analysis of NMR relaxation time data. The discrepancy is especially great for small, nearly spherical molecules. Also, the calculated translational diffusion coefficients for such systems are significantly smaller than measured D values.¹⁸

8.3.2 Gierer–Wirtz Microviscosity Factor

Two difficulties will arise from use of these hydrodynamic friction coefficients. One difficulty is uncertainty of the size of small molecules. Because of the free space between molecules in a liquid, it is not sufficient to equate the molecular volume to the molar volume divided by Avogadro's number. For example, a crystal made up of closely packed spheres is 26% empty volume. Accordingly, 74% of the above molecular volume is commonly used in calculating the molecular radius for rotational correlation time estimates. Several other methods are described¹⁸ for use in the Stokes–Einstein equation. However, using any realistic method of calculating molecular size does not solve the problem. The inclusion of a 'wetting' or 'sticking' layer of molecules would make the situation worse, because even smaller molecular volumes are generally needed to fit the experimental results to equations (91) and (92).

Another problem is that the molecule of interest is surrounded by particles of comparable size instead of a continuous fluid of infinitesimally small particles. Gierer and Wirtz¹⁹ estimated the rotational and translational friction coefficients of a 'solute' sphere surrounded by 'solvent' spheres by formulating the liquid viscosity in terms of the kinetics of the spheres. They regard the given molecule of interest to be a sphere of radius r and the surrounding molecules to be spheres of radius r_1 . The surrounding molecules form spherical layers, each of thickness $2r_1$, around the given molecule. If this central molecule is set rotating about the z axis with angular velocity ω , each layer will eventually acquire an angular velocity because of the friction between layers. In the steady state, the m th layer will have angular velocity ω_m . At equilibrium the total torque acting on the m th layer will be equal to the resistive torque on the central molecule, which is zero. The rotational friction coefficient for the central molecule is given by

$$C_s = 8\pi\eta r^3 f_r \quad (100)$$

where

$$f_r = \frac{\rho}{6} \left[\sum_m (1 + 2m\rho)^{-4} \right]^{-1} \approx \left[6\rho + \frac{1}{(1 + \rho)^3} \right]^{-1} \quad (101)$$

in which f_r is the rotational ‘microviscosity factor’, the summation is from $m = 0$ to $m = \infty$, and $\rho = r_l/r$. For translational motion, the Stokes–Einstein friction coefficient is multiplied by the microviscosity factor

$$f_t = [(3/2)\rho + 1/(1 + \rho)]^{-1} \quad (102)$$

The value for pure liquids is $f_r = 0.164$. Use of these microviscosity correction factors gives correlation times and diffusion coefficients that are generally close to experimental values when the assumed molecular volume is 0.74 times the molar volume divided by Avogadro’s number. However, when ρ differs from unity, the experimental f_r depends more strongly on ρ than equation (101) predicts. Generally, $\rho \neq 1$ for molecules in solutions.

8.3.3 Mutual Viscosity Formulation

The preceding calculations of the friction coefficient $\mathcal{C}_i$ use the viscosity of the fluid. This usage represents a deficiency of approach. As discussed by Hill,²⁰ every molecule in a pure liquid is surrounded by molecules of the same kind and the interactions between these like molecules determine both the liquid viscosity η and the friction coefficient $\mathcal{C}_i$. Despite the particular argument by which η and $\mathcal{C}_i$ are related, it is expected that they will vary in a similar manner from one substance to another. But in a dilute solution, η is determined almost entirely by the interactions between the solvent molecules while $\mathcal{C}_i$ is determined almost entirely by interactions between the solute and solvent molecules. Therefore, there is no reason to expect a general, simple relationship between η and $\mathcal{C}_i$ for solutions of different substances. To obtain an improved relationship, it is necessary to consider more closely the interactions that determine these quantities.

In the Andrade theory of liquid viscosity, the molecules in a liquid are regarded as vibrating with a frequency ν about equilibrium positions that change slowly with time. The transfer of momentum that occurs in a viscous liquid between layers moving with different velocities is due to temporary unions or collisions of adjacent molecules. These unions occur at the extremes of each vibrational swing so that, for an infinitesimal time, the two molecules move as one. Hill²⁰ applied this approach to a mixture of two liquids and found that the viscosity η_m of the mixture is:

$$\eta_m = f_A^2 \eta_A \sigma_A / \sigma_m + f_B^2 \eta_B \sigma_B / \sigma_m + 2 f_A f_B \eta_{AB} \sigma_{AB} / \sigma_m \quad (103)$$

where η_A and η_B are the viscosities of the pure liquids A and B, η_{AB} is the ‘mutual viscosity’, σ_A and σ_B are the average distances between molecules in the liquids A and B, σ_m is the average distance between molecules in the mixture, and σ_{AB} is the mean distance between a molecule of type A and

an adjacent molecule of type B in the mixture. The resultant value of $\mathcal{C}_s$ for a molecule of type B is:

$$\begin{aligned} \mathcal{C}_s = & 6 f_A \{ [(I_{AB} I_B) / (I_{AB} + I_B)] \\ & \times [(m_A + m_B) / (m_A m_B)] \} \eta_{AB} \sigma_{AB} \\ & + 3(3 - \sqrt{2}) f_B \{ [(I_{BB} I_B) / (I_{BB} + I_B)] \\ & \times [(m_B + m_B) / (m_B m_B)] \} \eta_B \sigma_B \end{aligned} \quad (104)$$

where I_B is the moment of inertia of a type B molecule, m is the mass of a molecule, and I_{AB} is the moment of inertia of molecule A about the center of mass of molecule B at the instant of collision. For a pure liquid ($f_B = 1$), the results are nearly the same as the Gierer and Wirtz approach, but for an infinitely dilute solution ($f_A = 1$), the viscosity is the mutual viscosity η_{AB} instead of the solvent viscosity. This approach explains²⁰ the different correlation times, found from dielectric relaxation measurements, for one solute in a variety of solvents having the same viscosity and for the relatively short correlation times found for solutes in high viscosity solvents.

In studies of the dielectric relaxation times of molecules of a wide range of size in solution, the use of equation (92) gives friction coefficients that agree²¹ with experiment when the molecular volume is at least three times that of the solvent molecule. Furthermore, the Hill theory is inferior for large solute molecules but it is superior for small solute molecules. Therefore, use of the rotational friction coefficients that are given in equations (92)–(99) to evaluate the correlation times for rotational diffusion of ellipsoids should provide a good approximation for large molecules in a solvent of small molecules.

8.4 Deficiencies of Viscosity/Rotational Diffusion Models

Since the earliest studies on molecular reorientational phenomena by nuclear magnetic relaxation, many have attempted to find a fundamental connection between orientational correlation times and macroscopic viscosity. Macroscopic viscosity, or shear viscosity, is defined as the resistance to shear if a thin liquid layer is moved (‘sheared’) between parallel plates. The physical dimension of viscosity is force times time divided by area. This tells us that we deal with momentum transfer. The momentum transfer tries to equalize the velocities of the moving layers. As indicated in Section 8.3.1, the hydrodynamic boundary conditions for the viscosity dependence of the orientational function of a spherical molecule have been defined in terms of a ‘rough sphere’; the surface of the reorienting molecule entrains its neighbors. A perfectly slipping sphere would have zero viscosity. On the other hand, we know that, on the molecular level, interactions take place through impulsive collisions between only a few neighbors. It is therefore not surprising that such a macroscopic rough sphere model overestimates $\mathcal{C}_s$. The microviscosity and mutual viscosity approaches are different attempts to formulate relationships that retain the idea of smooth spheres that, nevertheless, have surface friction. The situation is simpler for systems of small molecules of ellipsoidal shape since their reorientational motion displaces their neighbors; the rotational motion of a perfectly slipping ellipsoid would show a viscosity dependence.

The NMR relaxation behavior of several pure liquids of small molecules provides instructive cases. When the

molecules are rigid, all of the rotational diffusion models described above predict that the correlation times are directly proportional to the quantity η/T . However, this relationship is not always obeyed. Perdeuterobenzene provides a good example of this behavior. The temperature dependence of the deuteron T_1 value obeys²² an Arrhenius equation with an apparent activation energy $E_a = 7.78 \text{ kJ mol}^{-1}$. On the other hand, the temperature dependence of η/T is much greater; an Arrhenius equation is obeyed, but with $E_a = 13.05 \text{ kJ mol}^{-1}$. Besides varying temperature, the viscosity can be adjusted by changing the pressure on the liquid. The pressure dependence of the benzene viscosity²³ is described by an activation volume of $20.5 \text{ cm}^3 \text{ mol}^{-1}$. The pressure dependence of the deuteron T_1 of perdeuterobenzene is much less,²⁴ described by an activation volume of only $0.44 \text{ cm}^3 \text{ mol}^{-1}$. On the other hand, the pressure dependence of the translational diffusion coefficient of benzene²⁵ obeys an activation volume of $20.0 \text{ cm}^3 \text{ mol}^{-1}$, nearly identical to that of the viscosity. This means that the translational frictional coefficient is directly coupled to the viscosity, but the effective rotational friction coefficient is largely decoupled from the viscosity.

Acetonitrile, CH_3CN ,²⁶ is another instructive case. In the temperature range from 20°C to 50°C , the temperature dependence of η/T obeys an Arrhenius equation with $E_a = 8.66 \text{ kJ mol}^{-1}$. This molecule has an electric dipole moment that is parallel to the C–N axis of the molecule and the ^{14}N nucleus experiences an electric quadrupole interaction in the same direction. The temperature dependence of the dielectric relaxation time ($E_a = 8.28 \text{ kJ mol}^{-1}$) and of the ^{14}N T_1 (7.9 kJ mol^{-1}) are nearly equal to the above value for η/T . This shows that the rotational friction coefficient for reorientation of the C–N molecular axis at a given temperature is directly proportional to the viscosity. Also, the microviscosity model of Gierer and Wirtz,

$$\tau_c \equiv V\eta/6kT \quad (105)$$

where V is the molecular volume, yields at room temperature $\tau_c = 0.89 \times 10^{-12} \text{ s}$. This value is close (81%) to the value found from the ^{14}N measurements of T_1 . The deuteron T_1 values of CD_3CN , however, have a smaller temperature dependence with $E_a = 5.73 \text{ kJ mol}^{-1}$. This temperature dependence behavior shows that the rotational friction coefficient of the C–N axis of the molecule is directly proportional to the viscosity but that of the other molecular axes is relatively uncoupled from the viscosity. Also, at 25°C , the effective deuteron correlation time is $0.340 \times 10^{-12} \text{ s}$, which is much smaller than the value $1.104 \times 10^{-12} \text{ s}$ for ^{14}N . Evidently, the molecular reorientation rate about the C–N axis is much greater than that about an axis that is perpendicular to the C–N direction. If the molecule reorients like a rigid axially symmetric ellipsoid, use of equations (32) and (34)–(36) gives $R_3 = 10.35 \times R_2$. Also, the temperature dependence of R_3 is small, described by an Arrhenius equation with $E_a = 3.05 \text{ kJ mol}^{-1}$.

Toluene provides another informative case²⁷ of motions of small molecules. The temperature dependence of η/T is well described by an Arrhenius equation with $E_a = 11.51 \text{ kJ mol}^{-1}$. This value is larger than that of the T_1 of the ring deuterons of perdeuterotoluene (8.20 kJ mol^{-1}) and that of the methyl group deuterons of perdeuterotoluene (5.77 kJ mol^{-1}). Toluene has a

small electric dipole moment ($0.3\text{--}0.4 \text{ D}$) that is parallel to the methyl group symmetry axis. The dielectric relaxation time is approximately three times the NMR correlation time of the ring deuterons and its temperature dependence is essentially the same as that of this correlation time. Also, the T_1 values of the *ortho* and *para* ring deuterons are apparently equal. These dielectric and NMR relaxation results indicate that the ring of the toluene molecule reorients approximately like a sphere with $R_1 = R_2 = R_3$. However, the observation that the activation energy for the dielectric and NMR relaxation times is significantly smaller than that of η/T suggests that the molecular rotational friction coefficients of the ring are not directly related to the liquid viscosity.

Another significant observation is that the methyl deuterons have a much longer T_1 than the ring deuterons (4.88 s compared with 0.943 s). This longer T_1 and the smaller activation energy mean that the methyl group of the toluene molecule is internally reorienting rapidly about its symmetry axis. The intramolecular energy barrier to internal rotation of the methyl group in molecules such as toluene is very small, only $0.059 \text{ kJ mol}^{-1}$,²⁸ especially in comparison with the hinderance from interactions with neighboring molecules. Here, reorientation of the methyl group about its symmetry axis is completely independent from the reorientation of the remainder of the molecule, and the terms involving R_3 in equations (49) and (50) are omitted. Analysis²⁷ of the data using the ‘internal’ rotational diffusion model gives an apparent activation energy of 3.47 kJ mol^{-1} . Use of the ‘internal’ 120° jump model gives a similar value, 3.89 kJ mol^{-1} . Many other molecules have rapid internal reorientation of the methyl group, including methanol, acetone, acetic anhydride, ethanol, acetic acid, *t*-butanol, *p*-xylene, and acetophenone.

The rapid reorientation of the methyl group about its symmetry axis, the low values of apparent activation energy of this motion, and the decoupling of the rotational friction coefficient of benzene from the liquid viscosity may show that the model of rotational diffusion of a rigid ellipsoid may provide an incomplete description of molecular rotation of small molecules.

Relationships among viscosity, molecular reorientational motions, and molecular translational diffusion depend on the physical model that is assumed in the derivation. The Stokes–Einstein–Debye–Perrin model is based on the idea of particles surrounded by a continuous medium that is characterized by viscosity. The Gierer–Wirtz and Hill methods assume that the molecule of interest is surrounded by other particles and use specific physical models of interactions of spheres to interrelate the quantities. In all models, the system is at thermal equilibrium and subject to the general laws of thermodynamics and statistical mechanics. Different models may be appropriate for different molecular liquids. Steric considerations and the NMR observation²⁹ that benzene molecules rotate in the solid state suggest that liquid benzene molecules could rotate much faster about the C_6 molecular symmetry axis than about a C_2 axis. Such C_6 rotation requires less accommodation of the surrounding molecules than is required by a C_2 rotation. Similarly, for such molecules as toluene and acetonitrile, the rotation of a methyl group about its C_3 symmetry axis requires less accommodation by the surroundings than the rotation of the symmetry axis itself. Because the viscosity is likely to reflect the motions

that experience the greatest hindrances, the above C_6 and C_3 rotations could be largely uncoupled from the liquid viscosity. However, these rotations need not be completely free or frictionless. For example, the electric dipole moments of the individual C–H or C–D bonds could interact with the fluctuating local electric dipole fields due to the nearby molecules and hinder this motion.

9 CORRELATION FUNCTIONS FOR A 'NEARLY-FREE' ROTOR ATTACHED TO AN ELLIPSOID

The rotational diffusion model is a limiting case of the Langevin model. The internally reorienting part of the molecule may be treated as a classical rigid rotor that rotates about one axis. This rotational problem is analogous³⁰ to the case of translational motion.³¹ The distribution of rotational angular velocities follows the Boltzmann energy distribution law. The angular frequency ω of a rotor changes in time as described by

$$d\omega/dt = -[\xi\omega + F(t)]/I \quad (106)$$

where ξ is a rotational friction coefficient, I is the moment of inertia, and $F(t)$ is a randomly fluctuating torque. The fluctuating part is an instantaneous angular velocity independent, statistically defined force (its autocorrelation function decays much faster than that of the angular frequency) that causes random changes in the angular frequency. The value of the rotational angle $\phi''(\tau)$ of a rotor with initial angular velocity ω_i obeys a normal Gaussian distribution with a mean value

$$\langle\phi''(\tau)\rangle = \omega_i(I/\xi)\{1 - \exp[-(\xi/I)\tau]\} \quad (107)$$

When ξ is small, the value of $\langle\phi''(\tau)\rangle$ is $\omega_i\tau$. The averages $\langle\cos\phi''(\tau)\rangle$ and $\langle\cos 2\phi''(\tau)\rangle$ that appear in equations (38)–(40), obtained by a final averaging over the distribution of ω_i values, are:

$$\langle\cos\phi''(\tau)\rangle = \exp\{-(IkT/\xi^2)[\xi\tau/I + \exp(-\xi\tau/I) - 1]\} \quad (108a)$$

$$\langle\cos 2\phi''(\tau)\rangle = \exp\{-4(IkT/\xi^2)[\xi\tau/I + \exp(-\xi\tau/I) - 1]\} \quad (108b)$$

When the rotational friction coefficient is sufficiently great, we obtain an exponentially decaying function in τ as given in equation (44) with $R_i = kT/\xi$. This is the rotational diffusion limit. However, when the friction coefficient is sufficiently small, at short τ values we obtain exponentially decaying functions in τ^2 as given by

$$\langle\cos\phi''(\tau)\rangle = \exp[-(kT/2I)\tau^2] \quad (109a)$$

$$\langle\cos 2\phi''(\tau)\rangle = \exp[-(2kT/I)\tau^2] \quad (109b)$$

In this limit, the average values are independent of the friction coefficient and inertial effects dominate. The rotational

motions are decoupled from the viscosity of the liquid. The temperature dependencies predicted for these limiting cases are greatly different. Because the friction coefficient is likely to decrease with an increase in temperature, the temperature dependence in the rotational diffusion limit is expected to be much greater than in the inertial limit.

Although the temperature dependence may be used as a criterion between the applicability of these models, the value of R_i obtained from data analysis with the average angular velocity $(kT/I)^{1/2}$ provides another criterion. The rotational diffusion case may apply when the time required for the internal orientation to change by one radian calculated from the value of R_i obtained from data analysis, $(1/2R_i)$, is large compared to the time required by free rotation, $(I/kT)^{1/2}$. The motion of the methyl groups (CD_3) at room temperature falls between these two limits.²⁷ Further information about methyl group reorientation is available as follows. Equation (108) shows that I/ξ is the time constant for frictional changes in the rotational velocity of the CD_3 rotor. The quantity $(kT/I)^{1/2}$ is the average rotational angular velocity. The product of these two quantities, $(IkT/\xi^2)^{1/2}$, is the number of radians through which the CD_3 group rotates before its angular velocity changes appreciably. For the CD_3 groups of perdeuterotoluene at 298 K, this angle is 16° . This value is too large for rigorous application of the rotational diffusion model. Nevertheless, it is sufficiently small so that this model provides a convenient mathematical form for data analysis.

The experimental correlation times for many small rigid molecules in pure liquids and solutions obey a linear relationship with the liquid viscosity but have a nonzero intercept at zero viscosity. The intercept yields a correlation time² that appears to equal the time interval $(2\pi/9)(I/kT)^{1/2}$. This is the time required for a freely rotating molecule to turn through an angle of 41° , the angle for the correlation function of a second-order Legendre polynomial to drop to $1/e$ of its original (at $\tau = 0$) value. This result, which also shows that the correlation time is not directly proportional to viscosity at constant temperature, provides another indication that rotational diffusion may not accurately describe the motions of small molecules and the inertial effects are important in the rotational motions of small liquid molecules.

10 SCRUTINY OF THE MATHEMATICAL FORM OF CORRELATION FUNCTIONS

Realistically, at short enough times molecular collisions have not yet occurred and, consequently, molecular motion is purely kinetic. Because of this, the real correlation function has no first-order term in τ (it has zero slope at $\tau = 0$). Consequently, the rotational diffusion model fails with the first-order term and the spectral density derived from it is in error. We cannot use it to give a credible description of the details of molecular motion, especially for small molecules, since it is invalid for initial time intervals where the correlation function is least 'scrambled' by complicated orientation–collision events. This is dramatically shown by the nonexponential infrared and Raman spectral correlation functions² obtained in measurements on small molecules. NMR relaxation measurements made over a range

of frequencies do not reveal this dramatic behavior because the spectral density at ordinary Larmor frequencies is merely the integral of the correlation function. However, at sufficiently 'high' Larmor frequencies, the Lorentzian spectral density equation would not be obeyed. When this happens, and if the Larmor frequency is varied on both sides of the ' T_1 minimum', serious errors could occur if we interpret the relaxation data by use of the Lorentzian spectral density equation.

When the angle of free rotation is very large, the correlation functions derived for rotational diffusion of an asymmetric ellipsoid are no longer a reasonable approximation. In the spirit of Brownian rotational motion that is based on the Langevin equation in Section 9, the correlation functions for a rotating sphere with three degrees of rotational freedom are given by:

$$\langle F_h(t)F_h^*(t+\tau) \rangle = \langle F_h(t)F_h^*(t) \rangle \exp\{-6(IkT/C_s^2) \times [C_s\tau/I + \exp(-C_s\tau/I) - 1]\} \quad (110)$$

At long times, this function decays exponentially with time. At very short times, the results for a freely rotating sphere are obtained. At 'low' frequencies a plot of spectral density vs. friction coefficient C_s has a nonzero intercept equal to $(\pi/12)^{1/2}(I/kT)^{1/2}$. The spectral density function at high frequencies would deviate significantly from a Lorentzian function. When the friction is very large so that $C_s\tau/I \gg 1$, we obtain from equation (110) the results for rotational diffusion of a sphere.

There is a wide variety of correlations between NMR spectral densities of liquid molecules and macroscopic liquid properties such as viscosity. These correlations are sensitive to molecular size and intermolecular interactions. The spectral densities of large molecules appear to obey rotational diffusion equations with friction coefficients calculated with hydrodynamic models. Those for small molecules may be approximated by microviscosity and mutual viscosity formulations. Experiments that include NMR relaxation measurements at very high B_0 values and wide temperature ranges may yield more information on the rotational motions of molecules in liquids.

1 INTRODUCTION

Paralleling other developments in ^{13}C NMR,^{1,2} interest in ^{13}C spin relaxation data increased greatly with the availability in the early 1970s of Fourier transform methods.^{1–3} This interest initially arose for two reasons. First, it was necessary to have information about spin relaxation behavior in order to achieve sensitivity advantages approaching those theoretically possible in Fourier transform NMR experiments. Second, spin relaxation data can give chemical and dynamic molecular structural data that are either difficult or impossible to obtain from other kinds of measurements.

The ^{13}C nucleus is particularly well suited for spin relaxation studies for several reasons:

1. Since carbon atoms are usually found at the backbone of molecules, interpretation of ^{13}C relaxation behavior is generally not complicated by intermolecular relaxation processes, unlike the situation for ^1H and ^{19}F nuclei.
2. ^{13}C spectra are primarily observed under proton-decoupled conditions, where each carbon in the molecule is represented by a single spectral line whose spin–lattice (T_1) and spin–spin (T_2) relaxation times can be governed by single exponential time constants.⁴
3. The rather large chemical shift range of the ^{13}C nucleus makes it possible to resolve virtually all individual carbons, even in complex molecules. Thus, multiple sites are often available at which to probe a molecule's overall and internal motions.
4. Since ^{13}C is a rare spin (low natural abundance), consideration of ^{13}C – ^{13}C dipolar interactions or of the phenomenon of spin diffusion⁵ is usually not necessary. This greatly simplifies the interpretation of ^{13}C relaxation rates.

Carbon-13 relaxation times provide significant information in many areas of chemistry. Interpretation of ^{13}C relaxation data in terms of molecular dynamics (e.g. internal and overall molecular motions) provides the chemist with a unique and powerful probe into the detailed structure of organic molecular systems, and provides the theoretician with much needed motional data with which to test models for the microdynamic behavior of molecular systems. This potential for chemical insight, coupled with the ease of obtaining ^{13}C relaxation data

on commercially available FT NMR spectrometers, argues for a basic understanding of NMR spin relaxation parameters by most chemists. This article considers the topic of ^{13}C spin relaxation in three overall parts: (1) a description of ^{13}C spin relaxation processes, (2) a short section outlining experimental methods, and (3) discussions of several types of applications in organic chemistry.

The magnetic resonance parameters that are relevant to molecular dynamics are the nuclear spin relaxation times T_1 and T_2 and (usually) for the ^{13}C nucleus, the ^{13}C – ^1H nuclear Overhauser effect (NOE).

For a nucleus with a spin quantum number equal to $\frac{1}{2}$ (e.g., ^1H , ^{13}C , ^{19}F , ^{31}P , etc), there are two allowed orientations for each magnetic moment vector relative to an applied field, $\mathbf{B}_0$. If it is assumed that the spin system is in thermal contact with its environment and the nuclei do not strongly interact with one another, then in the absence of additional irradiation, a Boltzmann distribution of nuclei will be established among the two resultant energy states. The redistribution of populations arises from interactions of the nuclei with their surroundings. This interaction is the so-called spin–lattice relaxation process and is characterized by a relaxation time T_1 , which represents the timescale for energy transfer between the spin system and the lattice or environment. (For a liquid, the term ‘lattice’ is taken essentially as the translational, rotational, and other degrees of freedom of the molecular system.)

The resonant condition in NMR is accomplished by imposing a radiofrequency field $\mathbf{B}_1$ at right angles to $\mathbf{B}_0$. When B_1 is equal to the nuclear Larmor frequency, two effects occur in the spin system. First, some nuclei in the lower energy state absorb energy from $\mathbf{B}_1$, which results in a transition to the upper energy state and a decrease in the net population difference between the states. This process decreases the value of M_z , the magnetization along the z axis coincident with $\mathbf{B}_0$. The second effect of B_1 is to generate a phase-coherent magnetization in the transverse plane, M_{xy} . After excitation, the nuclei tend to get out of phase again, thereby decreasing M_{xy} . The time constant for this process is the spin–spin relaxation time, T_2 . Loss of phase coherence arises because fluctuating local magnetic fields augment or decrease $\mathbf{B}_0$, thus causing a spread of precessional frequencies among the individual nuclei and a corresponding loss of phase coherence. A second process tending to destroy the phase coherence arises from a mutual spin flip of two nuclei, if they are initially antiparallel and have precessing magnetic fields at the proper frequency. Although this interaction conserves the energy of the spin system, it does produce an uncertainty in the energy since it limits the lifetime of a state. The magnetization M_{xy} will decay to zero as the spins resume a random precession. When $M_{xy} = 0$, the net magnetization vector lies along the z direction; thus $\mathbf{M} = M_z$. However M_z may or may not at that moment equal M_0 . Simultaneous with the decay of M_{xy} is the restoration of M_z magnetization. The timescale for M_z to reassume the value M_0 is determined by the spin–lattice relaxation time. From the above arguments, $T_1 \geq T_2$.

Bloch viewed both of the magnetic relaxation processes as first-order decays. The usual equations for describing these decays are

$$\frac{dM_z}{dt} = \frac{-(M_z - M_0)}{T_1} \quad (1)$$

and

$$\frac{dM_{xy}}{dt} = \frac{-M_{xy}}{T_2} \quad (2)$$

These simple equations have been found to provide, in most cases, a good description of relaxation phenomena pertinent to much liquid-phase ^{13}C NMR.^{6,7} The primary concern of this article will be the spin–lattice relaxation time, T_1 , and the associated ^{13}C – ^1H NOE; in general, it is more difficult to measure ^{13}C T_2 values accurately.

Unlike most molecular relaxation processes in liquids, the timescale for the spin–lattice relaxation process is relatively long because the nuclear spin system is only weakly coupled to the other motions of the system. Experimental values of ^{13}C T_1 values are correspondingly of the order of 10^{-2} – 10^2 s and are usually in the range of 0.1 s to several seconds for typical organic compounds as neat liquids or in solution^{6,7} (provided the system is free of paramagnetic impurities). While this order of time constant indicates that the interactions governing the spin–lattice relaxation process are relatively inefficient, it is nevertheless only because of these weak interactions that nuclear spin relaxation occurs.

The coupling of the nuclear spin system to the lattice originates from the interaction of individual nuclear moments with fluctuating local magnetic fields, $\mathbf{B}_{\text{loc}}$, produced by the lattice at the nuclear site. If the various $\mathbf{B}_{\text{loc}}$ quantities have frequency components at values appropriate to the nuclear spin transition frequency, then energy can be transferred to the lattice and spin relaxation induced. The time dependence of the local fields arises from the overall and internal motions of the molecule, and other dynamic processes. To develop this link conceptually between $\mathbf{B}_{\text{loc}}$ and T_1 , it is necessary to consider the origin and some of the properties of the lattice fields.

In fluids, typical sources of $\mathbf{B}_{\text{loc}}$ are nuclear and electromagnetic dipoles, electric quadrupoles (for nuclei with spin $I > \frac{1}{2}$), anisotropy of the chemical shielding tensor, modulation of scalar coupling, and rotation of the molecule or group itself (spin rotation). The efficiency of any one of these sources in causing relaxation depends on both the amplitude of the fluctuations in $\mathbf{B}_{\text{loc}}$ and the timescale of those fluctuations. The mathematical description of the interaction of the spin with $\mathbf{B}_{\text{loc}}$ is similar for each relaxation mechanism.

Since the interaction of a ^{13}C nucleus with the magnetic field arising from an attached proton (^{13}C – ^1H nuclear dipole–nuclear dipole interaction) is most often the pathway useful in broad applications of ^{13}C spin–lattice relaxation,^{1,6,7} a brief account of the origin of the equation relating T_1 to this interaction is given immediately below.

1.1 The Dipole–Dipole Relaxation Mechanism

The prime source of ^{13}C spin relaxation in most diamagnetic liquids arises from the local magnetic fields produced by bonded or nearby protons. The instantaneous dipolar magnetic field (which may be as large as several gauss) that induces T_1 relaxation is proportional to the square of the magnetogyric ratios of both spins.

For a rigid system of intramolecular dipoles, molecular tumbling imparts the time-dependence to $\mathbf{B}_{\text{loc}}$ through the angle Θ between the through-space vector between the two

dipoles, and $\mathbf{B}_0$ (for carbons with directly bonded protons, this vector is of course coincident with the C–H bond itself). For the intermolecular case, and for intramolecular relaxation in flexible molecules, both the angle Θ and the distance between the dipoles are time-dependent, owing to relative translation as well as rotational motion. Intermolecular interactions tend to be attenuated rapidly owing to the r^{-3} dependence of $\mathbf{B}_{\text{loc}}$ for the two spins and the consequent r^{-6} dependence for T_1 relaxation of the ^{13}C nucleus. This result has important consequences for ^{13}C relaxation.

Another case of dipolar interaction is where the relaxing field has its origin with an unpaired electronic spin rather than a nuclear spin: for example, from any paramagnetic species present in the sample. Since the magnetic moment of the electron is roughly three orders of magnitude greater than nuclear moments, the fields are correspondingly more intense. When modulated by molecular tumbling, such fields can then induce very efficient nuclear spin relaxation, even at low concentration in a sample.

1.1.1 Properties and Formal Description of $\mathbf{B}_{\text{loc}}$

By assuming that the molecules constituting the liquid can be described as particles undergoing Brownian motion, the local dipolar field then has the following properties:⁸

1. $\langle \mathbf{B}_{\text{loc}}(t_0) \rangle = 0$, where $\langle \rangle$ is an average over time.
2. $\langle \mathbf{B}_{\text{loc}}^2(t) \rangle \neq 0$; i.e., the mean of the square is nonzero.
3. $\langle \mathbf{B}_{\text{loc}}(t_0) \cdot \mathbf{B}_{\text{loc}}(t + \tau) \rangle = 0$, provided that τ is sufficiently long.

At long τ , the value of $\mathbf{B}_{\text{loc}}$ at time $t + \tau$ does not in any manner depend on the value at time t . If τ is sufficiently short, then the quantity is expected to have a nonzero value.

Mathematically, these characteristics are embodied in the so-called time-dependent correlation function $G(t)$ of $\mathbf{B}_{\text{loc}}$.⁹ In a qualitative sense, such a function describes the persistence of a dynamical property of the system before being averaged out by molecular motions in the liquid, and is of particular value when two physical systems are weakly coupled, as is the case for the nuclear spin system and its lattice. The autocorrelation function of $\mathbf{B}_{\text{loc}}$ is given by the ensemble average

$$G(t) = \langle \mathbf{B}_{\text{loc}}(t_0) \cdot \mathbf{B}_{\text{loc}}(t_0 + \tau) \rangle_t \quad (3)$$

where the time-dependence is that produced by the molecular motion. The average is over an ensemble at the reference time t . Since $\langle \mathbf{B}_{\text{loc}}(t) \cdot \mathbf{B}_{\text{loc}}(t + \tau) \rangle$ is independent of the reference time, $G(t)$ is designated a correlation function of a stationary random process; $G(t)$ is independent of t_0 and is both a real and even function of τ .⁹ If the time origin is taken as $t = 0$, then

$$G(\tau) = \langle \mathbf{B}_{\text{loc}}(0) \cdot \mathbf{B}_{\text{loc}}(\tau) \rangle_0 \quad (4)$$

and $G(\tau)$ then describes the timescale for the decay of inherent motional order in the system. Information on the molecular system is dependent on the existence of $G(\tau)$, and as $G(\tau)$ decays toward zero so does knowledge of the dynamical processes at the prior time.

The Fourier transform of $G(\tau)$, the spectral density function, $J(\omega)$ provides the means of characterizing the frequency distribution and magnitude of the fluctuations in $\mathbf{B}_{\text{loc}}$; $J(\omega)$

represents a transformation from the time to the frequency domain. It is given by

$$J(\omega) = \int_{-\infty}^{+\infty} G(\tau) e^{i\omega\tau} d\tau \quad (5)$$

and represents the power available at angular frequency ω to relax the spin system. Equation (5) indicates that, if $G(\tau)$ decays slowly, information [through $J(\omega)$] will persist for a long time and the spectral lines will be narrow. If $G(\tau)$ decays rapidly, information is lost quickly and the spectral peaks will be broad.

Evaluation of equation (5) requires a description of the decay of $G(\tau)$. For a liquid, assuming exponential decay for $G(\tau)$

$$G(\tau) = \langle B_{\text{loc}}^2(0) \rangle_0 e^{-\tau/\tau_c} \quad (6)$$

where τ_c is the characteristic exponential time constant (correlation time) in which it is assumed motional order decays out of the system. It can be further assumed that the different spatial components of B_{loc} are uncorrelated, i.e., $\langle B_{\text{loc}}(x) B_{\text{loc}}(y) \rangle = 0$ but for isotropic motion they share the same correlation time, τ_c . Substitution of equation (6) into equation (5) and integration results in

$$J(\omega) = \langle B_{\text{loc}}^2(0) \rangle \frac{2\tau_c}{1 + \omega^2\tau_c^2} \quad (7)$$

From equation (7) it is evident that $J(\omega)$ is a maximum at $\omega = 0$ and is approximately constant over the range $\tau_c < \omega$; it decreases with increasing frequency as ω approaches $1/\tau_c$. The total spectral density, as a sort of probability distribution, is constant and independent of τ_c . Thus, variation in τ_c merely changes the distribution of 'spectral density' over the entire frequency spectrum.

This result indicates that T_1 goes through a minimum as a function of τ_c . Plots of T_1 versus τ_c as a function of spectrometer operating frequency are given in Figure 1. The left side of Figure 1, where T_1 is independent of spectrometer frequency, is called the region of motional narrowing. In this regime $J(\omega)$ is given by

$$J(\omega) = 2\langle B_{\text{loc}}^2(0) \rangle \tau_c \quad (8)$$

Liquids or solutions for which τ_c is within the motional narrowing limit include many organic molecules at or above room temperature. Use of increasing NMR magnetic field strengths, however, places more molecules outside the motional narrowing limit (see Figure 1). When the motional narrowing limit is valid, and when motion is isotropic, ^{13}C - ^1H dipole-dipole relaxation is described by

$$\frac{1}{T_1} = \sum_{i=1}^n \frac{\gamma_C^2 \gamma_H^2 \hbar^2}{r_{\text{CH}}^6} \tau_c \quad (9)$$

where the summation is over all nearby protons, and the r_{CH}^6 values reflect the various ^{13}C -H internuclear distances.

Figure 1 Spectral density $J(\omega)$ as a function of frequency for various values of the correlation time, τ_c (ω_0 corresponds to the nuclear Larmor frequency)

In the case of a ^{13}C nucleus that has one or more directly attached protons, longer range proton interactions can generally be ignored and equation (9) simplifies to:

$$\frac{1}{T_1} = \frac{N_H \hbar^2 \gamma_C^2 \gamma_H^2 \tau_c}{r_{\text{CH}}^6} \quad (10)$$

where N_H is the number of directly attached protons and r_{CH}^{-6} is the C-H bond length. In those cases where the molecular tumbling is anisotropic or where internal motions are present, ^{13}C dipolar relaxation (T_1 and T_2) is described by more complex equations, described elsewhere.⁸ Many applications can utilize equation (10), or approximate treatments that model motional anisotropy in terms of three orthogonal rotational diffusion constants (D_x , D_y , D_z).

1.2 Other ^{13}C Spin Relaxation Mechanisms

As described above, many carbons, particularly CH_x carbons, are relaxed completely by ^{13}C - ^1H dipole-dipole interactions. However, at increasingly high magnetic fields, and for other selected cases, a given carbon's relaxation may be dominated by other mechanisms.¹⁰ In applications of spin relaxation, it is of *paramount importance for the correct interpretation of results, that the investigator recognize all significant contributions to relaxation for the specific ^{13}C nuclei being examined.*

Briefly, the other ^{13}C spin relaxation mechanisms commonly encountered are: (a) dipolar interactions (DD) with other nuclides (e.g., ^{19}F , ^{31}P , sometimes ^{13}C , metal nuclei, etc.);

(b) dipolar interactions with unpaired electron spins (added paramagnetic agents, dissolved oxygen, etc.); (c) chemical shift anisotropy (CSA) relaxation of ^{13}C nuclei which occurs through the anisotropy of the ^{13}C shielding tensor; because CSA relaxation depends on B_0^2 as well as the square of the shielding anisotropy, it is significant, especially at higher B_0 , for sp^2 and sp carbons, and is often dominant at high B_0 for those carbons not having directly attached protons; (d) ^{13}C relaxation through scalar interactions is common for spin–spin relaxation (linewidths), but the formalism restricts scalar T_1 relaxation to carbons scalar-coupled (SC) with nuclei having a closely similar resonance frequency and/or a very large scalar coupling constant; carbons bonded to bromine atoms, for example, can have highly efficient scalar relaxation to ^{79}Br , whose resonance frequency is only 0.3% different from ^{13}C (for ^{81}Br the Δ frequency is 7.4%); and (e) spin rotation (SR) relaxation, which in very small molecules or for freely rotating groups such as the methyl group of toluene, can dominate ^{13}C relaxation. This mechanism is more common for heavy nuclides.

1.3 Relationship of T_1 to Individual Relaxation Mechanisms

In a particular compound, all or any combination of the ^{13}C relaxation mechanisms discussed above may be of potential importance. However, only a single relaxation time is measured for each carbon. This is assumed to be related to the individual mechanisms via the reciprocal relationship:

$$\frac{1}{T_1^{\text{obs}}} = \frac{1}{T_1^{\text{DD}}} + \frac{1}{T_1^{\text{SR}}} + \frac{1}{T_1^{\text{CSA}}} + \frac{1}{T_1^{\text{SC}}} + \frac{1}{T_1^{\text{other}}} \quad (11)$$

This equation ignores cross correlation between relaxation processes. Cross correlation relaxation can be important and useful.^{4b,c} It can be significant particularly between CSA and dipolar processes, but there are experimental methods for separating these effects.¹¹ Extraction of the relevant molecular information from measured T_1 values requires evaluation of the contributions from individual relaxation mechanisms.

In 1973, Levy, Cargioli, and Anet published a paper¹⁰ describing ^{13}C spin relaxation in benzene and a variety of substituted benzenoid compounds. In that early paper, evidence was found for different individual carbons having their spin relaxation controlled by each of the available spin relaxation mechanisms: dipole–dipole interactions, chemical shift anisotropy, spin rotation, and scalar interactions. It was seen that most carbons had their spin relaxation controlled by dipole–dipole interactions to attached or nearby hydrogens, except that for nonprotonated sp^2 carbons at (then) high fields (in 1973, 63 MHz operation for ^{13}C was considered high field) there were significant contributions from chemical shift anisotropy relaxation.

Another interesting exceptional case was found for the *ipso* ring carbon in bromobenzene, where the attached bromine was highly effective in producing scalar spin relaxation, at least for the ^{79}Br isotope. Because both ^{79}Br and ^{81}Br are present in roughly comparable amounts, the T_1 magnetization recovery was seen to be nonexponential (a combination of two dissimilar spin relaxation rates).¹²

In the 1973 paper on substituted benzenes,¹⁰ there was an expansion on work from Grant and others on free methyl rotation. The methyl carbon in toluene was observed to have effective spin rotation relaxation, as confirmed by variable temperature measurements. The effect of dissolved oxygen from the air was noted for these benzenoid compounds. In the case of the smaller nonpolar compounds, and for nonprotonated carbons in some of the larger substituted benzenes, oxygen from the air contributed significantly to ^{13}C overall spin relaxation. In benzene itself, dissolved oxygen resulted in a contribution of approximately 25% to the ^{13}C relaxation rate at 38 °C, while spin rotation relaxation had a comparable contribution. Observation of several phenylacetylene compounds showed that chemical shift anisotropy relaxation was a major contributor for nonprotonated sp carbons, even at modest magnetic fields.

1.3.1 ^{13}C – ^1H Dipole–Dipole Relaxation Outside of the Motional Narrowing Limit

For synthetic and biopolymers, where motion is slow and the ^{13}C – ^1H dipolar T_1 (and NOE) becomes field-dependent, it is more difficult to quantify ^{13}C – ^1H dipolar relaxation versus other contributors. However, especially for proton-bearing sp^3 carbons, it can usually be assumed that ^{13}C – ^1H dipolar relaxation is the only significant operating mechanism.

In these cases, when dipolar T_1 and observed NOE show complex behavior as a function of the NMR observed frequency (magnetic field), it is possible to model molecular dynamics in terms of the complex overall and internal motions occurring at various frequencies and, in the case of internal motions, of varying angular amplitudes. A number of models have been proposed,¹³ but many groups prefer to use a model-free description of complex dynamics initially proposed by Lipari and Szabo.¹⁴ While the model-free approach does not explain specific conformational motions, it is quite useful for the assessment of local conformational mobility in synthetic and biopolymers.^{15,16}

1.3.2 Complex Dynamics of Small Molecules; Nonexponential Decay of $G(\tau)$

In the mid-1970s it was recognized that, under a range of circumstances, the ^{13}C dipole–dipole T_1 values apparently indicative of motional narrowing in fact showed marked field-dependence.¹⁷ This occurs when there are cooperative motions, as in some samples of aggregated molecules having relatively freely moving side chains. In the first ^{13}C study of this type, the ^{13}C dipolar T_1 values for all 10 carbons in 1,2-decanediol were found to have a strong field-dependence despite being fully due to ^{13}C – ^1H dipolar interactions, and where lines were sharp and ^{13}C T_1 values were as long as 5 s (corresponding to a τ_c well within motional narrowing). The ^{13}C T_1 results of the 1,2-decanediol study¹⁷ are summarized in Table 1, along with T_1 values for 1-decanol, which can be used for comparison purposes.

The important and unexpected thing to note in Table 1 is the large difference between the 22.6 MHz and 67.9 MHz ^{13}C T_1 values of decanediol. By contrast, the ^{13}C T_1 values of 1-decanol show no field dependence, in accordance with standard theories for molecules undergoing rapid reorientation

Table 1 ^{13}C Spin–Lattice Relaxation Data for 1,2-Decanediol and 1-Decanol

Compound ^a	Temp (°C) ^b	Frequency (MHz)	^{13}C T_1 values (s) ^c									
			C-1	C-2	C-3	C-4	C-5	C-6	C-7	C-8	C-9	C-10
1,2-Decanediol	54	22.6	0.27	0.41	0.3	0.37	0.3	0.4	0.5	0.95	1.5	3.4
	54	67.9	0.5	0.7	0.5	0.6	0.6	0.7	1.0	1.8	2.7	5.3
1-Decanol	36	22.6	0.7	0.7	0.7		~1.0 ^d			1.5	2.4	3.9
	36	67.9	0.6	0.6	0.7		~1.0 ^d			1.4	2.3	3.8

^aSamples neat unless noted.^bTemperatures $\pm 1^\circ\text{C}$, measured directly before and after data collection.^cMaximum probable error $\pm 5\%$ – 10% . Decanediol and decanol data, average of two to four runs.^dPeaks insufficiently resolved for individual T_1 assignment.

in solution. These results can be interpreted in terms of a distribution of τ values for overall motion [or, equivalently, a nonexponential autocorrelation function $G(\tau)$] at the H-bond restricted end of the diol, with effective transmission of this nonideality to all the other carbons along the alkyl chain, either by the inherent intramolecular characteristics^{13b} of the chain segmented motion, or through intermolecular transmission from chain–chain entanglements.

1-Decanol is extensively hydrogen bonded in neat solution. The ^{13}C T_1 values of 1-decanol given in Table 1 do not show a significant field dependence. The two field T_1 data for decanol at 36°C thus do not require invocation of a complex cooperative motional description as in 1,2-decanediol.

The type of effect observed for the end carbons (C₇–H₁₀) of 1,2-decanediol may be observed in organized molecules, e.g., micelles, etc, and it is characteristic of complex dynamics in large biological or synthetic polymers, where relatively freely moving side groups can continue to show marked field dependence. For these cases, multiple field (frequency) ^{13}C T_1 , NOE and, where practical, T_2 measurements can provide an extremely sensitive probe of molecular dynamics, in favorable cases uniquely differentiating similar models for overall and internal dynamics.

2 MEASUREMENTS OF ^{13}C RELAXATION PARAMETERS

Pulsed Fourier transform NMR methods are available for accurately determining spin–lattice relaxation times and NOEs. In one-dimensional ^{13}C NMR, these methods have been used for over 25 years in order to determine simultaneously T_1 values for all carbons in the spectrum. Even though the measurements can be considered as routine on modern day spectrometers, there are many factors that can make the experimental values that are determined inaccurate.¹⁸ These factors include: (i) the choice of measurement pulse sequence; (ii) stability and accuracy of pulses and the spectrometer stability as a whole; (iii) data processing method used for calculation of the time constants from the experimental data; (iv) the presence of sample impurities; (v) temperature or solvent variation between experiments to be compared; (vi) sample geometry; and (vii) unusual spin relaxation characteristics, e.g., nonexponential relaxation.

Measurement of nuclear Overhauser effects similarly depends on the control of variables such as sample state and

temperature, the application of radiofrequency pulses and timing, and care in data processing. Further, both ^{13}C spin–lattice relaxation measurements and NOE experiments may become difficult for carbons having very long spin relaxation times, where the sample is limited in quantity, or where solubility is very low.

Various pulse sequences have been used to establish a nonequilibrium condition and monitor the magnetization as a function of the time variable τ , thereby measuring T_1 . Several pulse sequences directly measure NOE values, and one version of this experiment can simultaneously measure T_1 s and NOEs for all carbons (although the efficiency of this last experiment is not high). There are existing discussions of necessary precautions that should be taken in these measurements. Table 2 summarizes some of the experiments used for ^{13}C spin relaxation measurements.

Most of the experiments listed in Table 2 are straightforward; the experiments listed for the measurement of T_1 all produce a nonequilibrium magnetization with subsequent time recovery towards equilibrium being monitored by a 90° pulse. The IRFT¹⁹ and the pulse sequences most commonly used are relatively forgiving, experimentally. However, IRFT experiments can be quite lengthy when one or more carbons that are being measured have one long T_1 value. In these cases the shorter FIRFT experiment is preferred. The progressive saturation method was used in the early days of ^{13}C NMR but it is not generally used today because the technique is not as accurate in the case of mis-set pulse angles. Both progressive saturation and saturation recovery techniques utilize in most cases homospoil pulses (z homospoil) (indicated as HS in Table 2). The saturation recovery technique avoids some of the experimental problems of progressive saturation but the magnetization change measured is only half that of full inversion–recovery technique, leading to the choice of the latter in most cases. One advantage of the FIRFT pulse sequence is that for different ^{13}C nuclei in the same sample, the magnetization change being monitored can range from full inversion–recovery to essentially half of that value for very long T_1 values.

NOE measurements for ^{13}C are easily performed in most cases. Care must be taken in high dielectric samples not to heat the sample differently during relaxation pulse intervals, and in some cases authors have utilized decoupling power at a constant level but have offset the frequency sufficiently such that the protons in the sample are not affected.

Pulse sequences have been proposed to improve IRFT-type measurements²⁴ and to remove the effects of cross correlation between dipolar and chemical shift anisotropy relaxation.²⁵ Use of indirect observation (through the ^1H channel) to

Table 2 Some Methods for Determining ^{13}C Spin Relaxation Data

Method	Pulse sequence ^a	Comments	References
<i>(a) T_1 Measurements</i>			
Inversion recovery (IRFT)	$(180^\circ, \tau, 90^\circ, \text{AT}, \text{PD})_n$	PD > $4 \times$ longest T_1 to be measured	19

measure ^{13}C T_1 and T_2 values has been demonstrated.²⁶ New variations on direct T_2 pulse schemes have been proposed that improve their accuracy.²⁷

3 OVERVIEW OF APPLICATIONS FOR ^{13}C SPIN RELAXATION MEASUREMENTS

Utilization of carbon-13 spin relaxation data for both structural and dynamic information has been widespread in the literature over the past 20 years. Molecular systems that have been examined range from one-carbon molecules to highly complex synthetic and biological macromolecules, as well as simple and complex organometallics. The theoretical underpinnings for these measurements have advanced over this time period, but the simplest theories of spin relaxation are still sufficient in many applications. This has not caused special difficulty, since cross correlation has shown the greatest effect in the simplest molecules, usually under conditions that are not pertinent to most experiments (for example, in experiments not utilizing proton decoupling). By contrast, learning the intimate details of complex molecular dynamics can require highly sophisticated treatment of relaxation data.

Use of ^{13}C spin relaxation data to obtain qualitative dynamic information is quite facile; quantitative interpretation requires more care in terms of both experiment and elucidation of the dynamics through model assumptions, even in the case of model-free approaches. For molecules that are highly associated, or that are large enough inherently to be outside the extreme spectral narrowing limit, proper interpretation of the data is best done utilizing spin relaxation data obtained across dispersed frequencies (utilizing spectrometers operating at several magnetic fields).

3.1 Structure Determination

Carbon-13 spin relaxation data can be used as primary or confirmatory evidence for the assignment of chemical structures. The inverse sixth power relationship between ^{13}C – ^1H distances and the usual observed ^{13}C dipolar T_1 values can be converted into spectral assignment information, particularly for carbons not having directly attached hydrogens and yet dipolar-relaxed from protons on adjacent or nearby carbons, or from protons in the solvent. For carbons that have one or more directly attached hydrogens, the spin relaxation data may still be useful for spectral assignments, in many cases adding an independent check on assignments made by other methods. For molecules that are globular in shape and close to isotropic in tumbling behavior, the protonated carbon T_1 values often fall into three groups: CH_2 carbons with the shortest T_1 s, CH carbons having T_1 s approximately twice that of the CH_2 carbons (the relaxation rate is half because only one hydrogen contributes to the carbon's spin relaxation), and CH_3 T_1 s ranging from 1.5-times shorter than those found for CH_2 (occasionally, for a methyl that is not rotating) to T_1 values that are longer than T_1 values observed for the CH carbons in that molecule (rapidly rotating CH_3 groups).

An early example of the use of ^{13}C T_1 values to differentiate carbons not having directly attached hydrogens, is the molecule mescaline (**1**). The three types of nonprotonated carbons on the benzene ring of mescaline have differing numbers of hydrogens in the *ortho* ring position, as shown in structure (**1**). The ^{13}C T_1 s reflect this, the longest value belonging to the carbon having no adjacent ring *ortho* hydrogens. An example showing the ^{13}C T_1 s of protonated carbons varying with the numbers of directly attached hydrogens is the molecule cholesterol (**2**). Cholesterol shows T_1 values around 0.3 s for CH_2 carbons of the steroid ring skeleton while CH ring carbons show ^{13}C T_1 values closer to 0.55 s and methyl carbons (in this case, with considerable internal mobility) have T_1 values of approximately 1 s.²⁸ In

cholesterol, group segmental motion is also demonstrated; the carbon T_1 values of the cholesterol side chain increase with removal from the fused four-ring structure. Note that the side-chain carbons close to the steroidal skeleton maintain the expected ^{13}C T_1 values but near the end of the chain the CH_2 and CH carbons have significantly longer T_1 s, indicative of considerable group segmental motion. (The 1.6 s T_1 observed for the pendant methyl carbons results from combined segmental and methyl group internal rotation.)

Another early example of the utilization of ^{13}C spin relaxation times to assist spectral assignments was the study of the tetrasaccharide stachyose (3).²⁹ Stachyose contains two galactose residues and the carbon lines were differentiated as a result of segmental motion increasing the T_1 values of the terminal galactose relative to the internal galactose residue.

3.2 Dynamics of Small Molecules

Following pioneering work by the groups of David Grant⁴ and Endel Lippmaa,³⁰ both examining ^{13}C spin relaxation in very small organic molecules, studies began on organic systems of moderate complexity, including examination of group internal mobility and steric effects, solvent effects and hydrogen bonding, ionization, and microphase changes, such as occur in micelles or other ordered phases.

One of the interesting results reported in the 1973 substituted-benzenes paper¹⁰ related that preferred rotational motion around the axis coincident with the phenyl substituent was reflected in significantly shorter ^{13}C T_1 values for the protonated ring carbon *para* to the substituent, versus longer values for the carbons *ortho* and *meta* to the substituent. This effect was marked when the substituent was large or highly solvated, restricting motion through solvent-solute interactions

or, in some cases, ion-pair formation. The 60° angular relationship for the *ortho* and *meta* CH vectors with respect to preferred overall rotation around the symmetry axis coincident with the substituent (or, equivalently from the point of view of the ^{13}C T_1 s, for internal benzene ring spinning around the same axis), provides a sensitive probe of structure and solvation effects.¹⁰ It was reported for the long molecule 1,4-diphenyldiacetylene that the ^{13}C T_1 s for the *ortho* and *meta* carbons, approximately 5.3 s, were almost five-times longer than the ^{13}C T_1 values for the *para* carbon at 1.1 s. These results have some analogies to earlier work on methyl rotational rates, but the substituted-benzene structural unit allows for studies of a broader range of physical and chemical phenomena.

The 1973 paper also gave results for the phenol molecule, which when concentrated in solution is highly associated, giving shortened T_1 s, reflecting slow overall motion of the molecule. Further, the anisotropy of tumbling was shown to be higher in these concentrated solutions, where aggregation was important. The aniline molecule was also studied, as a neat sample, in several solvents, and as the anilinium cation. In the latter case, motion was restricted by roughly an order of magnitude and the anisotropy of overall and internal phenyl ring motion approached that in diphenyldiacetylene.¹⁰

Another early paper giving information about group internal rotations for ring compounds was published in 1972.³¹ In that study, two monosubstituted ferrocenes were examined. In both cases, ^{13}C T_1 s of the substituted ring carbons were approximately half that of T_1 for the carbons of the unsubstituted ring. Most of this differential was considered to be due to free internal rotation of the unsubstituted planar five-membered aromatic ring, around the ring-Fe bond. One of the molecules, *n*-butylferrocene, also displayed chain segmental motion, where the γ -methylene and δ -methyl carbon T_1 values indicated increased mobility.

In other early work, alkyl chain mobility and steric effects were examined for amides and oximes³² and in *n*-butylamine and the *n*-butylammonium ion.³³ In the study of several alkyl amides, differential effects were noted for group segmental motions *syn* and *anti* to the oxime function, and marked chain segmental motion was noted for *N,N*-di-*n*-butylacetamide, with ^{13}C T_1 s for the four carbons being observed to be comparable to the last four carbons in the hydrogen-bonded molecule decanol. In the case of the acetamide, restriction of chain motion results from the molecular mass centered at the nitrogen and not from hydrogen-bonding interactions. In the *n*-butylammonium ion, ^{13}C T_1 values were observed to decrease by over an order of magnitude in changing from the relatively nonpolar amine to the protonated species, with associated counterion and strong solvation. In *n*-butylamine itself, methylene group segmental motion along the four carbon chain was masked by rapid overall molecular tumbling, but the data for the *n*-butylammonium ion showed ^{13}C T_1 s comparable to those observed for the four carbon chain of *N,N*-di-*n*-butylacetamide, and also carbons 7 through 10 of 1-decanol.

3.3 Dynamics of Large Molecules

In the study of biological functions of macromolecules, it is essential to determine the nature and rate of internal motions of the molecule, as well as the overall average structure. Carbon-13 spin-lattice relaxation measurements, in conjunction with

NOE and when possible spin–spin relaxation measurements, have proven to be an important atomic probe of these internal motions. The relaxation of protonated ^{13}C nuclei is primarily dominated by the dipole–dipole interaction with the attached proton according to the following equation (valid inside or outside of the extreme narrowing limit):

$$\frac{1}{T_1} = R_1 = \frac{N_H}{20} \left(\frac{\mu_0 \gamma_C \gamma_H \hbar}{4\pi r^3} \right)^2 \times [J(\omega_C - \omega_H) + 3J(\omega_C) + 6J(\omega_C + \omega_H)] \quad (12)$$

where N_H is the number of directly bonded hydrogens, r is the average C–H bond distance, and $J(\omega)$ is the spectral density function at the three indicated frequencies.

Relaxation parameters are related to the overall and internal motions of a molecule through their dependence on the spectral density functions. For large or aggregated molecules that reorient slowly compared with the extreme narrowing limit, the description of the function for a large molecule undergoing overall isotropic motion with fast internal motion is the model-free approach by Lipari and Szabo¹⁴ in which the spectral density function is given by

$$J(\omega) = S^2 \left(\frac{\tau_c}{1 + (\omega\tau_c)^2} \right) + (1 - S^2) \left(\frac{2\tau}{1 + (\omega\tau)^2} \right) \quad (13)$$

where S^2 is a generalized order parameter describing the amplitude of the internal motion and τ_c is the overall correlation time. The quantity τ is related to the overall and effective correlation time for the internal motion by $\tau^{-1} = \tau_c^{-1} + \tau_e^{-1}$. This two-parameter fit of the relaxation data has yielded good success in describing the internal motion of certain residues in macromolecules. Clore et al.³⁴ found it necessary to expand the above equation to include the internal motions of two uncoupled processes:

$$J(\omega) = S^2 \left(\frac{\tau_c}{1 + (\omega\tau_c)^2} \right) + (1 - S_f^2) \left(\frac{2\tau_f}{1 + (\omega\tau_f)^2} \right) + (S^2 - S_f^2) \left(\frac{2\tau_s}{1 + (\omega\tau_s)^2} \right) \quad (14)$$

where ‘f’ refers to the fast motion and ‘s’ to slower motion that may not be outside the extreme narrowing limit.

The motion of large molecules can also be complicated by overall molecular shape. For globular proteins or polynucleotides of the order of 5–7 base pairs (where the length of the chain is roughly equal to the diameter), the overall motion can be described as isotropic, but with molecules in which the shape is not close to spherical the molecule itself undergoes anisotropic motion. Equation (14) can also be used to describe anisotropic motion with internal motion. In addition to this model-free formalism, a number of different equations of spectral densities have been proposed for anisotropic motion,³⁵ multiple internal rotations and restricted diffusion,³⁶ and librational motions.³⁷

Early work on the spin–lattice relaxation of carbon-13 of biological molecules provided a fragmentary analysis of internal motion. Instead of analyzing the relaxation data of a single ^{13}C resonance, usually composite ^{13}C resonances had to be studied. James³⁸ determined the internal motion

of 23 Thr residues of chymotrypsinogen to 20 ns based on the combination of spin–lattice relaxation, NOE, and off-resonance rotating frame spin–lattice relaxation techniques. These findings suggested that, on the average, the rate of motion of the Thr residues is limited, possibly by steric hindrance or by interaction of the polar hydroxy with other polar groups. Levy et al.³⁹ looked at the relaxation data for the interaction of ethidium bromide with nucleosome core length DNA, of ca. 145 bp, and determined that the overall conformational dynamics were not altered by low to moderate levels of ethidium. In addition, the flexibility of the sugar rings was reduced when ethidium intercalated in DNA. Levy et al.⁴⁰ also found that the ^{13}C relaxation parameters of double-stranded DNA molecules of 100–300 bp were well fitted by a model which assumed that DNA undergoes rapid local motions such that the C–H vectors wobble inside a conic boundary with a half angle of 20–25°. In addition to these rapid local motions, slower overall axially symmetric rotation occurs. These are a few examples of early studies of ^{13}C relaxation in which qualitative or semiquantitative dynamic information could be ascertained from a combination of different relaxation techniques.

A comprehensive interpretation of ^{13}C relaxation data had been hampered by the inherent low sensitivity of the carbon-13 nucleus, the low natural abundance of carbon-13, and the low resolution of one-dimensional spectra. These problems have been alleviated to a certain extent by the development of proton-detected two-dimensional heteronuclear relaxation experiments,⁴¹ which increase the sensitivity by approximately $(\gamma_H/\gamma_C)^{5/2}$ ⁴² and afford increased resolution by the addition of the second dimension. The pulse sequence consists of an initial DEPT sequence⁴³ to transfer the magnetization from protons to the carbon, a relaxation period T that is varied between the two-dimensional data sets, and the evolution time, followed by a second DEPT sequence in which the magnetization is transferred back from the carbon to the protons for detection. The intensities of the peaks, $I(T)$, are described by the usual T_1 equation of the inversion–recovery experiment.

Palmer et al.⁴⁴ have used this method, along with spin–spin relaxation and NOE studies, to characterize the intramolecular dynamics of Xfin-31, which is a 25-residue synthetic zinc finger peptide that is capable of binding nucleic acids and is recurrent in regulatory proteins. The studies suggest that the motion of the backbone carbons, excluding the terminal residues, are highly restricted, but with the residues forming a loop between the β -sheet and the helix showing slightly higher mobility. The motion of the side chains of the hydrophobic residues, Val and Leu, are also restricted, although they are more mobile than the backbone. These results suggest that the peptide is quite compact.

An additional development that has allowed comprehensive analysis of T_1 relaxation is site-specific ^{13}C enrichment. This has permitted certain sites in a macromolecule to be extensively studied. Nicholson et al.⁴⁵ have ^{13}C -enriched 11 leucine residues of the protein staphylococcal nuclease, which is a small enzyme of $M_r = 16800$. The leucines, which are nearly all buried within the closely packed interior, were studied with, and without, ligand binding by two-dimensional relaxation methods as described above. The parameters were fitted using the formalism of Lipari and Szabo¹⁴ [equation (14)]. The results showed a rapid rotation of the methyl group

about the $C^\gamma-C^\delta$ bond, plus a slower motion associated with the reorientation of the $C^\gamma-C^\delta$ bond axis itself. A significant increase in the order parameter, S^2 , was seen upon binding of the ligand to leucine in the vicinity of either Ca^{2+} or the pdTp heavy atoms, which indicates a localized restriction of motion in the vicinity of the ligand-binding sites.

Many groups have used relaxation data in order to characterize the motion of synthetic polymers.^{46,47} Early on, Jacob Schaefer,^{13a} using the results of carbon-13 spin-lattice relaxation times, linewidths, and NOE factors for isotactic polystyrene, *cis*-polyisoprene, and *cis*-polybutadiene, proposed a $\log \chi^2$ density function to describe the distribution of motion. The width of the distribution is a relative measure of the extent of cooperative segmental motion of the chain. In this 1973 study, it was shown that polybutadiene exhibits more long-range cooperative motions than the other two polymers studied.

3.4 Solvent Effects and Intermolecular Interactions

Unlike ^{15}N , in which intermolecular dipolar relaxation can contribute significantly to the nitrogen T_1 values carbon-13 intermolecular effects are usually negligible. Therefore, the use of ^{13}C spin-lattice relaxation to study intermolecular interactions, such as solvent effects hydrogen bonding, and ion-dipole pairing depends on the fact that the localized motions around the site of the interaction are restricted and the overall tumbling decreases due to the increased size of the complex. Both of these effects will result in a decrease in the ^{13}C spin-lattice relaxation times. These effects have been seen upon molecular association⁴⁸ and solute-solvent interactions⁴⁹ via hydrogen-bond formation.

In a study of molecular association, it was shown in 1971 by Alger, Grant, and Lyerla⁴⁸ that the carbon nuclei of formic and acetic acids have shorter T_1 s, therefore relax faster, than the corresponding methyl esters. The carboxylic acid, which is dimerized by hydrogen bonding, rotates more slowly than the methyl esters. This behavior is seen in long- and branch-chain alcohol and acids, such as decanoic acid, decanol, and 3,7-dimethyloctanol, in which the hydrophobic end shows increased mobility, i.e. longer T_1 s than the polar end which is hydrogen bonded and therefore less mobile. Other solvent effect studies had been discussed earlier.^{10,17}

The intermolecular interaction of biological molecules in solution is of biological significance. Casarotto and Craik⁵⁰ looked at the interaction of tricyclic antidepressant drugs imipramine (4) and amitriptyline (5) with sodium dodecyl sulfate (SDS) (6) micelles. The ^{13}C relaxation parameters, including T_1 and NOE measurements at two different field strengths, were fitted to the model-free formalism of Lipari

and Szabo.¹⁴ The smallest T_1 value occurs in the middle of the aliphatic chain of neat SDS with a slight increase near the headgroup and a significant increase near the terminal methyl region. This corresponds to a low value for the order parameter for the terminal methyl, which reflects increased amplitude of mobility at the end. Upon addition of the drugs, there was a significant decrease in the T_1 values with an overall increase in the S^2 values. The aromatic carbons of the drugs showed the greatest change in T_1 upon association with the micelles. This indicated a marked decrease in overall tumbling rate. The rapid internal bridge flipping of the seven-membered ring is not significantly affected in the micelles. It was concluded from the relaxation studies that there is a notable increase in the micellar volume with a reduction of motion in the SDS alkyl chains. The drugs become extended in the micelles with the tricyclic moiety occupying the hydrophobic region of the micelle and the terminal dimethylammonium ion interacting at the micelle-water interface.

4 SUMMARY

Carbon-13 relaxation data provide unique insight into the structure and, especially, the structural dynamics of organic molecular systems, including complex biomolecules. The ability of these studies to probe molecules at each atomic site, and quantitatively to reflect dynamical information, is made especially useful by the central role of carbon atoms in these molecules and by the relatively simple mechanistic relaxation pathway for most ^{13}C nuclei. Carbon-13 relaxation complements other techniques in yielding to scientists the most basic structural secrets of complex molecules.

1 INTRODUCTION

Coupled spin relaxation is the generally accepted term for the spin–lattice relaxation of a scalar-coupled spin system such as a ^{13}C -containing methylene group, $^{13}\text{CH}_2$. It is a powerful method to probe motional dynamics in solution, particularly in molecules with internal motions such as polymers.

Nuclear spin relaxation was recognized as a powerful probe of motional dynamics since the observation of unexpectedly sharp resonance lines in liquids in the early days of magnetic resonance spectroscopy in the 1940s. These phenomena were explained almost immediately in terms of the effect of thermal motion by Bloembergen, Purcell, and Pound.¹ This sensitivity to motion has its basis in the fact that the energy of a spin state in a static magnetic field usually depends on an orientation, whether it is the orientation of a chemical shift tensor or a dipole–dipole interaction between two spins or a quadrupole coupling tensor. Orientational fluctuations, that is ‘motional dynamics’, cause fluctuations in the spin energy levels that can couple to each other or the surrounding lattice to produce the various phenomena of spin relaxation. Measurement of spin relaxation times in order to obtain information about dynamics has been widely exploited (see *Carbon-13 Relaxation Measurements: Organic Chemistry Applications*, etc.).

In the 1960s Woessner, amongst others, recognized the potential of using a series of relaxation interactions that are rigidly oriented relative to each other to obtain information about the anisotropy, or relative rates in different directions, of motion (see *Brownian Motion and Correlation Times*). The requirement of a series of independent spin systems all oriented rigidly relative to each other in a molecule is a stringent one however, and the method did not receive wide application.

In the 1970s several groups showed that a more productive approach was to use the multiplicity of interactions amongst a *single* spin system of three or more scalar-coupled spins to generate sufficient information to determine the full diffusion tensor of a small molecule^{2,3} (see *Relaxation Processes in Coupled-Spin Systems*). In addition, coupled spin relaxation has the advantage that a three spin system such as $^{13}\text{CH}_2$ can be incorporated in a flexible chain and thus provides a powerful

probe of internal motion. Application of these techniques to internal dynamics in small molecules has recently been reviewed.⁴

The basis for the method can be summarized briefly. The relaxation of dipolar coupled spins is generally described in terms of autocorrelation spectral densities which are the Fourier transforms of correlation functions relating the orientation of an internuclear dipole to itself at a later time. For multiple coupled spins, for example $^{13}\text{CH}_2$, a complete description of the relaxation also includes cross-correlation terms between *pairs* of dipolar vectors. The traditional approach has been to regard these as unimportant and, using our example, to decouple the ^1H spins to enhance the ^{13}C sensitivity. Invariably, the proton-decoupled methylene ^{13}C spin will relax with an ‘effective’ single exponential recovery law as the multiple exponential relaxation behavior of the coupled spins is obscured with the collapse of the proton-induced multiplet under decoupling.

Study of the fully coupled multiplets provides significant additional information. For a methylene group, four independent spectral densities are required to describe the relaxation, even in the extreme narrowing limit. These can be used to calculate four correlation times describing reorientation of the x , y , and z axes of a molecule fixed reference frame.

This article describes the application of coupled spin relaxation to the reorientational dynamics of polymer chains in solution. These dynamics have been of considerable interest in recent years. Technologically important properties such as elasticity, phase transition temperatures, and solution and melt viscosities are thought to be correlated with molecular motion.⁵ Thus, understanding the relationship between chain structure and chain motion is an important factor in predicting polymer properties.

Spin–lattice relaxation has been widely used to investigate such systems and, typically, in these studies the ^1H or ^{13}C T_1 values of the polymer are studied as a function of temperature and/or field strength. The results are then fitted to expressions derived from the theoretical models. Discrimination between models has been difficult, however. While experiments such as those described are very sensitive to the motional *timescales*, they lack descriptive details of the *geometry* of motion. This latter information is often needed to discriminate one model from another and can be provided by coupled spin relaxation methods.

In addition, computer simulations of the dynamics of simple polymers are now practical. Recent simulations of chain dynamics have included studies of polyethylene (PE), polyisoprene, and poly(ethylene oxide) (PEO).⁶ The Cartesian correlation times (described below) calculated from coupled spin relaxation measurements can be obtained directly from such simulated dynamics trajectories.

Coupled spin relaxation methods have now been applied to a series of linear polymers, most notably polyoxides. In the following, the theory and methods used in these studies are described and recent results are then summarized. The results show quite strikingly the dependence of dynamic properties on chain structure.

2 SPIN–LATTICE RELAXATION OF $^{13}\text{CH}_2$

As noted above, the $^{13}\text{CH}_2$ spin system makes an excellent probe of chain dynamics. The relative positions of the nuclei

in the methylene group are independent of the orientation or rotational state of the chain. Spin relaxation of the group then depends on its overall reorientation, not the motion of the three nuclei relative to each other. Dipole–dipole interactions among the ^{13}C and ^1H spins are sufficiently strong that they are the dominant relaxation mechanisms under most circumstances. These characteristics make the spin relaxation behavior itself relatively simple to interpret. In addition, there are experimental advantages to this spin system. The coupled spin relaxation can be characterized entirely from observing the ^1H coupled ^{13}C multiplet and individual ^{13}C signals are often easily resolved, even in complex samples. The ability to excite ^{13}C and ^1H spins separately makes it possible to dispense with most selective excitation experiments.

Relaxation in scalar-coupled spin systems has been described using Bloch–Redfield theory and then recasting the density matrix in terms of ‘magnetization modes’. A full description is given elsewhere and will not be repeated here except to summarize pertinent details (see *Relaxation Processes in Coupled-Spin Systems* and *Relaxation Mechanisms: Magnetization Modes*).

An energy level diagram for the AX_2 spin system (of which $^{13}\text{CH}_2$ is an example) is given in Figure 1. Application of Bloch–Redfield theory to the AX_2 spin system in the eigenstate representation yields an expression for the time evolution of the populations of the various states, N_κ ,

$$\frac{dN}{dt} = \mathbf{W}[N - N(\infty)] \quad (1)$$

where the elements of N are the diagonal members of the spin density matrix: $N_\kappa = \sigma_{\kappa\kappa} = \langle \kappa | \hat{\sigma} | \kappa \rangle$. The elements of the matrix $\mathbf{W}$ are a subset of the full Redfield matrix, $W_{\kappa\lambda} = R_{\kappa\kappa\lambda\lambda}$, and may be considered as simple transition probabilities.

For convenience magnetization modes, ν , corresponding to a maximum number of observables are constructed by taking linear combinations of the diagonal density matrix elements. Thus

$$\nu_\kappa = \sum_\lambda T_{\kappa\lambda} N_\lambda \quad \text{or} \quad \mathbf{\nu} = \mathbf{T}\mathbf{N} \quad (2)$$

where $T_{\kappa\lambda}$ are the elements of the transformation matrix. If $\mathbf{\Gamma} = \mathbf{T}\mathbf{W}\mathbf{T}^{-1}$, then

$$\frac{d\mathbf{\nu}}{dt} = \mathbf{\Gamma}[\mathbf{\nu} - \mathbf{\nu}(\infty)] \quad (3)$$

As line intensities depend on the difference between diagonal density matrix elements, the magnetization modes can also be expressed as combinations of line intensities. The members of a convenient set of modes for the AX_2 spin system which are observable in isotropic solution are:

$$\left. \begin{aligned} {}^a\nu_A &= \frac{1}{k_A}(L_1 + L_2 + L_3) \\ {}^a\nu_X &= \frac{1}{k_X}(L_4 + L_5) \\ {}^a\nu_{+-} &= \frac{1}{k_A}(L_1 - L_2 + L_3) \\ {}^a\nu_{\pm\mp} &= \frac{1}{k_X}(L'_4 - L''_4 - L'_5 + L''_5) \\ &= \frac{1}{k_X}(L_1 - 2L'_2 + L_3) \\ {}^s\nu_{+0-} &= \frac{1}{k_A}(L_1 - L_3) = \frac{1}{k_X}(L_4 - L_5) \end{aligned} \right\} \quad (4)$$

where line labels are given in Figure 1 and k_A and k_X are scaling factors. The quantities ${}^a\nu_A$, ${}^a\nu_{+-}$, and ${}^s\nu_{+0-}$ are all directly observable from the A spectrum (^{13}C in a $^{13}\text{CH}_2$ study). The quantity ${}^a\nu_A$ is proportional to the sum of the intensities of all the lines in the A multiplet. The quantity ${}^a\nu_{+-}$ is proportional to the difference between the intensities of the outer and inner lines of the multiplet, while ${}^s\nu_{+0-}$ is related to the difference between the two outer lines of the multiplet. The quantity ${}^a\nu_X$ is simply the total X (^1H) magnetization. Application of a 90° X pulse simultaneous with an observe pulse on the A spins exchanges triplet intensities in the A manifold and allows, by difference, evaluation of ${}^a\nu_{\pm\pm}$.

The elements of the relaxation matrix, $\mathbf{\Gamma}$, are made up of linear combinations of spectral densities arising from the interactions important in the system under study. These might include dipole–dipole, chemical shift anisotropy, spin rotation, and random field interactions among others. The relaxation matrix for the AX_2 spin system including only contributions from dipole–dipole and random field interactions and corresponding to the set of magnetization modes used here is given in full elsewhere.⁴

In the limit of extreme narrowing, the dipolar relaxation of an AX_2 or $^{13}\text{CH}_2$ spin system is completely described by four frequency-independent spectral densities. Two of these are autocorrelation terms related to the CH or HH' internuclear vectors (J_{CH} and J_{HH}). The others are cross-correlation terms relating one CH vector to the other (J_{HCH}) or to the HH' vector (J_{CHH}). A complete set of random field spectral densities would include an autocorrelation term at the carbon (j_C), an autocorrelation term at each hydrogen (j_H), and a cross-correlation term between the two hydrogens (j_{HH}).

The first label gives the state of the A spin and subsequent labels the states of the two X spins. Allowed single quantum transitions are labeled. (b) A schematic diagram of the AX_2 spectrum in isotropic solution

3 OBTAINING MOTIONAL INFORMATION FROM COUPLED SPIN RELAXATION DATA

As noted above, the spectral densities are the Fourier transforms of correlation functions relating the orientation of an internuclear dipole to a second dipole at a later time. In the simplest case, these correlation functions decay as simple exponentials which can be characterized by a correlation time, τ_c . The value of the spectral density then depends on the magnitude of τ_c and the frequency at which it is sampled. When the dynamics are more complex, the correlation function can be a complex sum of exponentials with various time constants. The resulting spectral densities do not reflect the values of these time constants in any simple way.

Two general approaches to this problem have been established. One is to sample a spectral density function at a range of frequencies, perhaps by performing conventional T_1 experiments at several field strengths. This is often effective in enabling the investigator to estimate the timescales involved in a dynamic process, but is less effective in establishing the associated geometrical factors. The other approach, embodied in the coupled spin relaxation experiment, is to sample a wider variety of spectral density functions. The ratios of the different spectral densities at a given frequency are often a sensitive function of the geometry of the motion.

It remains to establish the relationship between the measured spectral densities and appropriate motional parameters. Again, two approaches have been used. The first, dating to the very first use of spin relaxation to elucidate dynamic parameters, is to assume a particular motional model and then calculate the associated correlation function and, by taking the Fourier transform, spectral density function. The assumption of diffusive isotropic motion, which leads to an exponential correlation function and a Lorentzian spectral density function, is the classic example of this approach, but it has also been applied to much more complex models.

A second approach that has been used recently is to take the four spectral densities measured in the coupled spin relaxation experiment (J_{CH} , J_{HH} , J_{HCH} , and J_{CHH}) and to reexpress them in terms of four autocorrelated Cartesian spectral densities, which are in turn simply related to four correlation times (τ_{xx} , τ_{yy} , τ_{zz} , and τ_{xy}).⁷ These transformations are model-independent and are extremely useful in several ways. First, the difficulty of interpreting cross-correlation functions is removed. Second, the results are presented in a molecule fixed Cartesian axis system commonly used in dynamics simulations (see Figure 2) and are readily interpretable. The correlation times describe the reorientation of geometrical constructs having the shape of d orbitals. Thus τ_{xx} represents the motion of a d_0 construct fixed on the x axis or the bisector of the HCH angle. Lastly, it should be emphasized that in the transformation to this basis no biases or assumptions about the dynamical behavior of the molecule are introduced, as are encountered in using diffusional models.

As will be discussed below, in spin relaxation studies of unlabeled polymers it is difficult to determine J_{HH} reliably. Under these circumstances some assumption must be made in order to accomplish the transformation. A reasonable assumption is to set τ_{xx} and τ_{yy} equal to each other and defining a $\tau_{\perp}$ term. The quantities τ_{xx} and τ_{yy} have been shown to be very similar in value in simulations of flexible chains.

Figure 2 Orientation of the Cartesian axis system in the frame of reference of the methylene group

Reduced spectral densities are defined as

$$\hat{J}_{ijkl} = \frac{20}{9K_{ijkl}} J_{ijkl}(\omega = 0) \quad (5)$$

where $K_{ijkl} = \gamma_i \gamma_j \gamma_k \gamma_l \hbar^2 / r_{ij}^3 r_{kl}^3$ and i, j, k , and l represent the spins involved. If the reduced autocorrelation spectral densities $\hat{J}_{xx}$ and $\hat{J}_{yy}$ are set equal to each other than it can be shown:

$$\left. \begin{aligned} \tau_{\perp} &= \tau_{xx} = \tau_{yy} = \frac{3}{4(\alpha^4 - \beta^4)} (\hat{J}_{AX} + \hat{J}_{XAX} - 4\beta^2 \hat{J}_{AXX}) \\ \tau_{\parallel} &= \tau_{zz} = \frac{3}{2\alpha^2} (\hat{J}_{AX} + \hat{J}_{XAX} - (2 - 4\beta^2) \hat{J}_{AXX}) \\ \tau_{xy} &= \frac{1}{4\alpha^2 \beta^2} (\hat{J}_{AX} - \hat{J}_{XAX}) \end{aligned} \right\} \quad (6)$$

where $\alpha = \cos(\theta/2)$, $\beta = \sin(\theta/2)$, and θ = HCH angle.

4 EXPERIMENTAL METHODS FOR POLYMER STUDIES

Spectroscopic samples are typically 1% w/v polymer in good solvents. Samples are degassed either by flushing the solvent with dry nitrogen and then assembling and sealing the sample under nitrogen, or by subjecting the sample to five freeze-pump-thaw cycles and then sealing under vacuum.

Spin relaxation measurements use variations on the inversion recovery pulse sequence. Four different initial perturbations of the coupled $^{13}\text{CH}_2$ spin system are used: (1) a ^{13}C 180° pulse inverting the ^{13}C triplet; (2) a ^1H 180° pulse inverting the proton doublet; (3) a low power ^1H pulse inverting only the low-frequency line of the ^1H doublet; and (4) a J pulse preparation on the ^1H magnetization (resembling a spin echo) resulting in the inversion of the outer lines of the ^{13}C triplet. In each case the initial perturbation of the spin system is followed by a variable delay period and a ^{13}C sampling pulse as in a normal inversion recovery experiment. For each experiment 17 or 18 different delay times are used. The delay times are ordered randomly to reduce systematic errors. Recycle delays are adjusted to be at least 10-times the nominal T_1 value of the sample.

FIDs are subjected to appropriate exponential multiplication before Fourier transformation. Line amplitudes are then obtained, typically after applying a linear baseline correction over a 500 Hz region centered on the appropriate ^{13}C multiplet. Relaxation parameters are obtained from a multiparameter least squares curve fitting routine using an implementation of the Levenberg–Marquardt algorithm. Theoretical values of the intensities of the modes are calculated first using the normalized, symmetric set of modes described by Werbelow and Grant⁸ and then taking appropriate linear combinations to generate the modes described here. Parameters for the fit include not only dipolar and random field spectral densities, but also several experimental parameters.⁹ To account for any systematic instrumental imperfections or differences in widths of inner and outer lines of the multiplet, the line amplitudes for each data set are scaled by two parameters β and δ such that the ^{13}C multiplet has the expected 1:2:1 intensity ratio when fully relaxed. The term L_3 (see Figure 1) is multiplied by δ to equalize the outer line intensities and then both outer lines are multiplied by β to equalize the intensities of the sum of the outer lines and the inner line of the multiplet. A third parameter associated with each data set is a normalization constant such that $^a\nu_{\text{C}}(\infty)$ is scaled to unity. Additional parameters are pulse efficiencies and differential pulse efficiencies.

Spectral densities included in the fit include four frequency independent spectral densities describing the dipolar relaxation of a methylene group ($^{13}\text{CH}_2$) in the limit of extreme narrowing (J_{CH} , J_{HH} , J_{HCH} , and J_{CHH}). Random field spectral densities are also included to account for other relaxation mechanisms operating in the sample, primarily remote dipolar interactions. For the methylene spin system, a complete set of random field spectral densities would include an autocorrelation term at the carbon (j_{C}), an autocorrelation term at each hydrogen (j_{H}), and a cross correlation term between the two hydrogens (j_{HH}). At high fields or in a more anisotropic electronic environment caused by insertion of an oxygen into the polymer chain, cross correlation between chemical shift anisotropy (CSA) and dipolar relaxation mechanisms is possible. Where appropriate, this requires inclusion of four more spectral densities in the fit: $J_{\text{CH,C}}$, the cross term between the CH dipolar interaction and the carbon CSA; $J_{\text{CH,H}}$, the cross term between the CH dipolar interaction and the proton CSA; $K_{\text{CH,H'}}$, the cross term between the CH dipolar interaction and the CSA on the other proton (H'); and finally $J_{\text{HH,H}}$, the cross term between the HH dipolar interaction and the proton CSA.¹⁰

Rigorous characterization of dipolar interactions as random fields requires that both the rotational and translational motion of the interacting spins be independent. This independence of motion is not satisfied for protons bonded to carbons adjacent to the methylene group of interest. A study of isotopomers of 5- ^{13}C nonane has shown that inclusion of random field terms in the relaxation matrix is not enough to allow accurate measurement of all four dipolar spectral densities in the presence of protons on neighboring carbons.⁹ However, that study showed that as long as the random field term j_{C} is held equal to zero in the fitting procedure, then J_{CH} , J_{HCH} , and J_{CHH} may be reliably evaluated; J_{HH} remains strongly correlated to j_{H} . The results reported here follow this practice.

5 RESULTS FROM POLYMER STUDIES

These methods have been applied to a series of homologous polyethers with increasing numbers of methylenes between the oxygens: poly(oxyethylene) (POM),¹¹ poly(ethylene oxide) (PEO),¹² and poly(tetramethylene oxide) (PTMO),¹² and to poly(*cis*-1,4-butadiene) (CBD).¹³ In the absence of data on polyethylene, CBD serves as a model for the dynamics of the infinite polymethylene chain. Recent simulations of polyethylene and polyisoprene suggest the dynamics are quite similar despite the structural differences and justify this analogy.⁶ Data from the smaller hydrocarbon [11- ^{13}C]heneicosane are also included for comparison.¹⁴ These polymers exhibit a wide range of equilibrium conformations with POM most stable in a helical conformation and CBD in an extended, all-*trans* conformation. PEO and PTMO are more flexible and intermediate in conformational preferences. As such they provide an interesting opportunity to probe the impact of chain conformation on dynamics with only minimal variations in structure.

Each of the polymers studied has a single type of methylene group, except for PTMO which has two distinct types of methylene groups with the carbons adjacent to the oxygen (C- α) absorbing at 67.4 ppm and the central carbons (C- β) absorbing at 25.3 ppm. Only POM and heneicosane were isotopically labeled to provide truly isolated $^{13}\text{CH}_2$ spin systems.

Three ‘magnetization nodes’ of each $^{13}\text{CH}_2$ spin system can be obtained while observing only the ^1H coupled ^{13}C spectrum of a given polymer: $^a\nu_{\text{C}}$, the total ^{13}C magnetization; $^a\nu_{+-+}$, the difference between the inner and outer line intensities of the ^{13}C triplet; and $^s\nu_{+0-}$, the difference between the intensities of the outer two lines of the ^{13}C triplet. Figure 3 shows typical relaxation curves for C- α of PTMO.

The three dipolar spectral densities which have been reliably evaluated in all cases can be reexpressed in terms of three second rank autocorrelation times ($\tau_{\perp} = \tau_{xx} = \tau_{yy}$, τ_{zz} , and τ_{xy}). The transformation to Cartesian correlation times requires that the geometry of the spin system be known. In most cases these geometries must be inferred from small molecule analogs. As hydrogens are not located accurately in most X-ray diffraction studies, it is generally necessary to rely on other structural techniques such as electron or neutron diffraction. For methylenes in hydrocarbon chains, electron diffraction studies of small alkanes provide the HCH angle of 108.5° and a CH distance of 1.12 Å. For protons bonded to carbons adjacent to oxygen, the value of 1.11 Å for the CH distance given by the electron diffraction study of the small molecule analog 1,2-dimethoxyethane has been adopted. The HCH angle was not determined in that study. The Cartesian correlation times calculated using these parameters are given in Table 1. Uncertainties reported are standard errors in the last significant figure of the associated value.

The timescales of tens of picoseconds reported in Table 1 are consistent with those generally found for local segmental motion of polymers in dilute solution. Because of differences in temperature and viscosity among the samples, comparing the absolute values of the correlation times is not as interesting as comparing ratios of correlation times which gives insight into the anisotropy of motion. Table 2 gives these ratios.

If we examine the anisotropies of motion of the most conformationally distinct polymers, POM and CBD, we see

Figure 3 Magnetization mode intensities for C- α of PTMO. Intensity units are defined by setting $^a\nu_C(\infty)$ to unity. Table 1 Cartesian Correlation Times of Polymers in Solution

	$\tau_{\perp}$ (ps)	τ_{zz} (ps)	τ_{xy} (ps)
POM (phenol- d_6 , 86 °C)	21(1)	36(6)	12.1(8)
PEO (D_2O , 25 °C)	42(9)	115(11)	44(3)
PTMO(C- α) (toluene- d_8 , 28 °C)	21(2)	64(3)	10.4(6)
PTMO(C- β) (toluene- d_8 , 28 °C)	15(2)	45(2)	15.2(6)
CBD (CD_2Cl_2 , 20 °C)	23(2)	55(6)	11(1)
C11-heneicosane (diglyme- d_{14} , 40 °C)	21(1)	48(3)	9(1)

Table 2 Motional Anisotropies of Polymers in Solution

	$\tau_{zz}/\tau_{\perp}$	τ_{zz}/τ_{xy}	$\tau_{\perp}/\tau_{xy}$
POM	1.6	2.6	1.6
PEO	2.7	2.6	1.0
PTMO(C- α)	3.0	6.2	2.0
PTMO(C- β)	3.0	3.0	1.0
poly(<i>cis</i> -1,4-butadiene)	2.4	5.0	2.1
C11-heneicosane	2.3	5.1	2.2

that they are quite different. POM has reduced anisotropies of motion compared with CBD methylenes, which in turn have anisotropies of motion which are very similar to those of the central methylene of the smaller hydrocarbon heneicosane. These differences have been interpreted in terms of the relative importance of transitions between rotational isomeric states and librational motion within a given potential energy well in the spin relaxation of these polymers. The lowest energy conformation of POM in solution is predicted to be helical, with no readily available rotational transitions that do not involve major chain translocation. In such a situation it is reasonable to expect librational motion to be an important relaxation mechanism. In CBD the extended chain structure make possible ‘crankshaft’-type correlated motions of a few bonds. Supporting the interpretation that these might be important are simulations of hydrocarbon chains which show contributions from both correlated and uncorrelated chain motions. The correlated motions in these simulations have a similar ratio of $\tau_{zz}/\tau_{\perp}$ to that observed for CBD and heneicosane.¹⁵

New patterns emerge when examining the anisotropies of motion for PEO and PTMO. Overall the pattern for C- α of PTMO is much like those seen previously in hydrocarbons, although with slightly greater anisotropies. PEO and the C- β position of PTMO have very similar anisotropies of a reduced magnitude and a much different pattern from any observed previously. The ratios $\tau_{zz}/\tau_{\perp}$ and τ_{zz}/τ_{xy} are nearly identical and the ratio $\tau_{\perp}/\tau_{xy}$ is essentially unity. The relative anisotropies of C- α and C- β of PTMO are the opposite of what might be naively expected. Based on the similarity of the energetics of conformations involving C- α and its adjacent atoms to those in PEO, and of conformations involving C- β to those in PE, one might expect the opposite result.

Do the differences in dynamics in PEO and PTMO originate at the librational level or in transitions between rotational isomeric states? It is difficult to imagine that the differences in

Figure 4 Examples of chain motion on a tetrahedral lattice. An example of three bond motion is at the bottom and of four bond motion is at the top

librational motion between C- α and C- β , adjacent carbons in the PTMO chain, are large enough to give rise to the measured difference in anisotropies. A plausible model does exist for differences in rotational transitions.

Geny and Monnerie have simulated the motion of the various linear polyoxides as motions involving three or four bonds on a tetrahedral lattice.¹⁶ Examples of such motions are shown in Figure 4. The three bond motions are essentially the 'crankshaft'-type motions referred to above. Four bond motions involve the pivoting of a segment back and forth, without the option of continuing around the chain axis. Three bond motions occur in all their simulations of the polyoxides although with markedly less 'efficiency' in POM due to the stability of its helical form. Four bond motions such as shown are forbidden in PE due to the 'pentane effect' (which rules out g^+g^- sequences because of steric interactions of the hydrogens on carbon i and $i + 4$ along the chain). In the polyoxides these motions are allowed as long as at least one oxygen atom is at the 'foot' of the pivoting segment. Geny and Monnerie found these motions even more common than three bond motions in PEO, significant in PTMO, and again rarely observed in POM.

Of course, full recognition must be given to the limitations of the model of the polymer chain as moving on a tetrahedral lattice. In this model all motions must be cooperative, in the sense that any configurational transition is accompanied by compensatory transitions elsewhere in order not to force large motions of the chain. In contrast, Brownian dynamics simulations of the PE chain showed that at least two-thirds of the configurational transitions in PE were 'isolated' rotations about bonds along the chain accompanied by orientational relaxation of neighboring segments. Simulations of polyisoprene suggest that three bond motions are largely absent in polyisoprene. Furthermore, analysis of the motion in isolated configurational transitions and in 'three bond motions'

in PE finds them to be nearly identical, leading into question the importance of cooperative motions in analyzing polymer dynamics.

Even so, the reduced anisotropy of PEO relative to the hydrocarbons may be due to the combination of three- and four-bond motions available to the former. In particular, the ratio $\tau_{\perp}/\tau_{xy}$ becomes unity only when there is efficient averaging with respect to the z axis of the coordinate system we have defined. Remembering that the z axis is perpendicular to the HCH plane or parallel to the vector between adjacent atoms on either side of the methylene along the polymer chain, efficient averaging around this axis occurs whenever the methylene is located at the 'point' of the four bond section which is pivoting.

The results for PTMO may then be explained by noting that only C- β can be at the 'point' of the pivoting section when there is an oxygen at the 'foot', making the four bond motion possible. The motion of a methylene at the 'side' of the four bond segment is similar to that caused by a three bond motion and thus although PTMO as a whole appears to undergo three and four bond motions, C- α can only experience 'three bond like' motion and thus is very similar in anisotropy to hydrocarbons studied previously. Thus while four bond motions may be minor components of the overall dynamics, by introducing a distinctly different reorientational motion they may have an apparently disproportionate impact on the measured anisotropy. A more complete analysis of the importance of these motions must await more realistic simulations of the polyoxide chains. A molecular dynamics simulation of PEO in water has been published recently, but it was on a fairly short chain (13 units) and the question of cooperative transitions was not addressed.

1 INTRODUCTION

In conventional NMR experiments the spin resonance is observed by irradiating selected nuclear magnetic spins of a sample material, which is exposed to a fixed high magnetic flux density B_0 (Zeeman field, magnetic induction), with appropriate time-dependent rf fields $B_1(t)$ tuned in resonance with the Larmor frequency $\nu \sum \omega/2\pi$ of the nuclei considered. This resonance frequency ν usually varies linearly with the magnitude of the Zeeman field B_0 according to the Larmor condition $\nu = \gamma B_0/2\pi$, where γ is the characteristic magnetogyric ratio of the nuclear spin species; therefore, with decreasing field strength the standard procedures become more and more impracticable or even impossible for several reasons. The difficulties are primarily due to the related well known weakening of the NMR induction signal, which for a constant number of nuclei falls approximately as $B_0^{3/2}$, but serious problems also occur due to the tendency of the resonance to become broader at lower frequencies for a given linewidth. Hence it is not surprising that, generally, instruments operating at B_0 fields or Larmor frequencies ν as high as possible are favored, and most endeavours in the past were concerned with ways to strengthen B_0 to improve the signal quality. Presently, most spectrometers work under high-field conditions in the range between about 4 MHz up to 800 MHz for protons and up to 100 MHz for several spins with smaller γ , corresponding to a maximum Zeeman field of nearly 20 T. However, many good reasons can be given to support the less spectacular developments which oppose this familiar trend, that is, how to overcome the physical and technical barriers connected with NMR frequencies below the common megahertz range. The Earth's magnetic field $B_{\text{Earth}} \approx 5 \times 10^{-5}$ T can be easily compensated for to less than 1% of its value, allowing NMR spectroscopy with Larmor frequencies as low as, for example, 20 Hz for protons to be performed.

Numerous techniques have been successfully realized to solve the problems of NMR under low-field conditions below $\nu \approx 1$ MHz, ranging from simple enlargement of samples to sophisticated polarization transfer. One of these techniques, which is still relatively rarely used despite the great instrumental progress in recent years, is field cycling (FC) magnetic resonance or, more correctly, fast field cycling, where B_0 is not fixed but periodically cycled. Several reviews

on the subject have been published.^{1–3} FC primarily makes it possible to extend the scope of frequency-dependent relaxation measurements from the megahertz regime to almost zero Larmor frequency. FC devices also, however, supplement or even replace presently used standard procedures, because once in operation the new approach is often less time-consuming than common practice: changes of the Larmor frequency do not require inconvenient retuning of electric circuits. Furthermore, the FC principle is very versatile, since cycling of both the strength and orientation of the Zeeman field B_0 , combined with special $B_1(t)$ sequences, allows for possibilities which go far beyond the original intentions.^{1,2} Typical subjects of FC studies are concerned with, for example, frequency-dependent relaxation times (relaxation dispersion), zero field spectra (resolution improvement), heteronuclear cross-relaxation effects (quadrupole dips), diffusion constants (magic angle averaging), and the angular dependence of these and related NMR parameters where lower Larmor frequencies introduce more favorable spectroscopic timescales than conventional magnetic resonance methods.

The origins of the FC technique go back to the early 1950s, when several groups started low-field work and searched for ways to improve the results. A simple yet slow mechanical field switch was first described in 1951 by Pound.⁴ However, it took more than 10 years to develop instruments which allowed the FC principle to be applied to other than the most convenient cases. Essentially based on the pioneering concepts of Redfield et al.,⁵ several laboratories succeeded in developing fast, versatile FC devices for measurements of fast relaxing signals of liquids and solids, and various prototypes of flexible, powerful machines have been described in the literature.^{1–3,6–13} However, a commercial apparatus is not yet available. Due to the peculiar spin dynamics of some particularly ordered systems such as organic conductors⁷ (spin waves) or anisotropic liquids¹¹ (order fluctuations), where as a rule a dramatic shortening of the longitudinal spin relaxation time occurs at low fields, studies of such materials require very fast cycling devices, which are difficult to construct. However, the presently available equipment will allow the application of FC NMR in most cases,

2 BASIC FC PRINCIPLES

2.1 Field Periods

FC requires the sample material to be in different Zeeman fields (two or more) at different times t . This implies that the normally constant external flux density $B_0 \sum \mu H_0$ or magnetic field H_0 (μ is the permeability of the sample) has to be modulated periodically (cycled) in strength or direction (ideally both) in an adequately fast manner in a definite way (Figure 1). In the simplest case the nuclear spins are polarized and detected as usual by means of a field sufficiently high to yield a satisfactory signal quality. Unlike standard high-field NMR, however, between the period of polarization and the period of detection one inserts a period of evolution, during which the external field is decreased from the selected high value to an adjustable lower level. In this way any related Larmor frequency can be tuned easily over a broad range $\nu_{\text{min}} < \nu < \nu_{\text{max}}$, where the limits are mainly determined

2 FIELD CYCLING EXPERIMENTS

Figure 1 Typical B_0 field cycle with polarization, evolution, and detection periods, and transition intervals from high to low and low to high

by the properties of the available magnet system and the exactness of the Earth's field compensation. As a consequence, features characteristic of the spins for frequencies between almost zero and an upper limit $\nu_{\max}$, at present typically 10–50 MHz, can be conveniently studied by well established high-field detection methods at a single fixed field. Obviously, the primary sensitivity problem is now transformed into the exacting task of switching an adequately high magnetic induction rapidly and reproducibly with sufficient accuracy. Sometimes it proves advantageous to use the highest accessible B_0 not for the polarization and detection period, but only for the shorter evolution state, so that FC is a technique for both lowering and increasing the Larmor frequency compared with the fixed detection field.^{3,11} During the different phases of the cycle the sample has to be irradiated by standard magnetic rf sequences $B_1(t)$ to prepare and observe the nuclear magnetization or spin order, to determine the underlying frequency dependent spin parameters such as relaxation times, coupling constants, spectral shifts, jumping rates, etc.^{1,2}

2.2 B_0 Field Switches

To keep such experiments as flexible and transparent as possible, the cycle must fulfill several conditions on the level and speed of the field changes. It is obvious that both B_0 and its time derivative dB_0/dt at the transitions should be made as large as is technically feasible to obtain good signals in the presence of fast magnetization decays. However, there are exceptions where it is necessary to slow down the switching to avoid effects on the spin order (see Section 2.4). Originally, the cycles were produced mechanically by moving or shooting the sample between a strong and a weak magnet⁴ [Figure 2(a)]. This technique is relatively simple to realize, and is therefore still used,^{14–16} taking advantage of strong cryomagnets for the high-field states, but it has some significant drawbacks. Above all, the switching times t_s (typically $t_{\text{off}} \approx t_{\text{on}} \geq 0.1$ s) are generally too long for work on fast relaxing spins. The more powerful alternative⁵ is to generate the transitions by quickly turning the current on or off through a magnet coil by means of an electronic switch [Figure 2(b)]. To understand the main problem of such a device one has to recall some elementary physics. If a voltage U is applied to a coil with inductance L and series resistance R_s , the current I through the coil, and

Figure 2 B_0 field switch devices using either (a) a shuttle between two magnets (mechanical switch) or (b) a fast power supply control of the electric current I through a magnet coil (electronic switch)

hence the related field B_0 , increase exponentially with the time constant L/R_s . Owing to this increase, an equilibrium state is obtained more rapidly with a higher damping resistance, but this does not mean that the switching becomes faster by increasing R_s . Consideration of Faraday's induction law shows us that the fastest current change in the magnet is independent of R_s and determined by $(dI/dt)_{\max} = U/L$; this maximum slope is maintained longer for a smaller R_s , and hence in principle a cryomagnet with $R_s = 0$ should give the best results. However, other features of cryomagnets, e.g. the maximum allowed current density, are less favorable. So to obtain fast field transitions one has to be concerned with high driving voltages U , and magnets with both low inductance L and low resistance R_s , i.e. with high-current air-cored coils instead of iron magnets. Since the highest electric power $P = UI$ is needed only for the (short) transition intervals, it is most effectively provided by an energy storage control which supplies a higher voltage (U_c) for the transition than for the steady states (U_0). All this was already known to Redfield,⁵ but in 1968 adequate electronic components to build a powerful FC network were not available.

2.3 T_1 Cycle

A typical frequency-dependent FC measurement of the longitudinal relaxation time T_1 can be performed by combining a B_0 cycle with standard B_1 rf pulses as shown in Figure 3. When the Zeeman field is switched from its maximum value B_P to a selectable lower level B_R (in this case called the

Figure 3 The FC principle for frequency- (or field-) dependent measurements of the longitudinal relaxation time $T_1(\nu)$ or $T_1(B)$. The diagram illustrates the $B_0(t)$ cycle, the related magnetization decay $M(t)$ from M_0 to M_∞ , and the FID signal $U_{\text{sign}}(t)$ after a $\pi/2$ B_1 rf pulse

relaxation period), the initial longitudinal magnetization $M_0 = \chi H_0 = (\chi/\mu)B_0$ along the external magnetic field H_0 of, say, proton spins (χ is the nuclear spin susceptibility) decays exponentially with a time constant $T_1(H_R)$, characteristic of the Larmor frequency ν_R in the adjustable field H_R , to the new equilibrium $M_\infty = \chi H_R$. This decay is sampled as a function of the relaxation interval Δt by the FID amplitude after a $\pi/2$ rf pulse, applied in resonance with the Larmor frequency ν of the high detection field $B_D = B_P$, immediately after the transition to this detection state. Then the procedure is repeated over the available range of ν_R s to give the full dispersion profile $T_1(\nu_R)$. If ν_R is near to ν_{max} and hence $M_0 - M_\infty$ becomes small, it is advantageous to precede the off switch by a π or $\pi/2$ rf pulse, which enhances the $M(t)$ change. The field switching times t_{off} and t_{on} must be shorter or at least comparable to the considered relaxation interval Δt and the observed T_1 value to get exact results. All these steps and the necessary data acquisition and processing, including the frequency changes, do not require hardware readjustments and can be conveniently made computer controlled. Frequency-dependent

studies of other relaxation processes, e.g. transverse to B_0 (T_2) or along the dipolar field B_d (T_{1d}), are less common in the literature and require more sophisticated cycles and different rf pulse sequences,^{1–3} which are briefly commented on later in this article.

2.4 Adiabatic Condition

The main purpose of making the B_0 field switches of a cycle fast is to avoid uncontrolled magnetization decay and hence signal losses by relaxation. For a T_1 cycle this essentially requires $t_{\text{off}}, t_{\text{on}} \leq T_1$. However, it is often overlooked that too fast transitions may also modify the magnetization or spin order undesirably in spite of negligible relaxation effects, namely by changing the angle of the magnetization M relative to the Zeeman field, and thus by inducing transitions between different Zeeman levels. Field changes preserving the initial angle during the transitions, which for normal FC T_1 measurements should be zero, for example, are called adiabatic, whereas nonadiabatic transitions perturb the angle.^{1,2} Both types of switches are applied in FC experiments: standard relaxation studies demand adiabatic cycles;^{1–3} nonadiabatic cycles^{2,14,15} are mainly practised in zero field and Earth's field FC NMR, where rotations of M are necessary. The condition for adiabaticity requires that field variations perpendicular to the initial Zeeman field B_0 must be slow compared with the effective Larmor frequency $\nu = \gamma B$ according to^{1,2}

$$\frac{|B \times dB/dt|}{B^2} \ll \gamma B = 2\pi\nu \quad (1)$$

which restricts the time derivative dB/dt if the direction is perpendicular to B because of the finite value of ν , particularly at low frequencies. Obviously, equation (1) is always valid, independent of the magnitude of dB/dt , so long as the orientation of B is not changed. The condition becomes critical in the case of angular-dependent measurements, and in any case at low Larmor frequencies near $\nu \approx 10$ kHz, where for solids internal local field contributions B_{loc} are comparable in magnitude to the external field B , and thus locally fast field rotations come into play. Similar effects may occur if the Earth's field is not properly compensated for or not correctly adjusted parallel to the Zeeman field of the spectrometer. Such problems have frequently been neglected and need more careful study. Adiabaticity sometimes requires that the cycle transition must be slowed down in the low-field range by appropriate current regulation, though such a step entails a dilemma between signal losses at transitions by either nonadiabaticity or by relaxation.

3 TECHNICAL PROBLEMS AND INSTRUMENTS

3.1 Magnet Switch Optimization

Magnets for fast FC NMR should provide the following from a given electric power P : (i) a magnetic flux density (induction) B or the related magnetic field $H = B/\mu$ as high as possible; (ii) the large flux variation rate dB/dt needed for the cycle; and, in addition, (iii) a satisfactory field homogeneity

$B/\Delta B$ over the sample volume. These three requirements are strongly interrelated, and the problems of finding the most favorable switching network and coil geometry have still not been solved completely. This explains why many constructions described in the literature^{5–13} are more or less based on semiempirical rules concerning the magnet system, though there are some sophisticated approaches. The basic aspect of the optimization problem is well demonstrated by considering estimations of B and dB/dt for a simple, long cylindrical coil with inductance L , resistance R_S , and field volume V in the solenoid approximation (length $\gg$ diameter), where the field is assumed to be constant over the whole coil volume, i.e. its inhomogeneity $\Delta B/B$ is neglected. If such a solenoid is driven by a power supply with maximum current $I_{\max}$ and maximum voltage $U_{\max}$ during the transitions, the greatest possible flux density and flux variation rate following from Maxwell's equations are determined by^{1,2}

$$(B)_{\max} = (\mu L/V)^{1/2} I_{\max} = (\mu L/V)^{1/2} (U_0/R_S) \quad (2)$$

$$(dB/dt)_{\max} = (\mu/LV)^{1/2} U_{\max} = (\mu/V)(P_{\max}/B_{\max}) \quad (3)$$

with $P_{\max} \sum I_{\max} U_{\max}$, $I_{\max} \sum U_0/R_S$, and U_0 the steady state supply voltage. These relationships illustrate the intricate role of the magnet inductance L when trying to optimize the switch characteristics, i.e. to maximize both B and dB/dt , since the field strength increases with $L^{1/2}$, whereas dB/dt decreases with $1/L^{1/2}$. Essentially, equations (2) and (3) show the merits of high-current magnets in comparison with low-current coils, and also establish that the available electric power, the maximum field, and the field volume limit the switching or transition times t_{off} , t_{on} of the cycle. The time $t_S = (dt/dB) B$ for a transition from zero to $B_{\max}$, or the inverse, becomes larger in the considered approximation ($\propto B_{\max}^2$ and V), but smaller with higher power ($\propto 1/P_{\max}$). Therefore the technical progress achieved in recent years is due to a great extent to the improved knowledge of handling smaller, yet still homogeneous magnet coils in combination with more powerful electric current supplies; advanced supplies typically should provide^{11–13} an average power of 10–50 kW and a peak power of 100–500 kW to obtain fields of the order of 1–2 T, with switching times better than 1–10 ms and a homogeneity up to some 10^4 over 1 cm^3 . One should note that equations (2) and (3) involve an interesting dependence on the permeability μ , which, however, has not been exploited in practice due to the technical problems of filling the coil volume around the sample with a magnetic material.

3.2 Energy Storage

Since the switching power $P_S = P_{\max} = I_{\max} U_{\max}$ is only needed over the rather short field transition times, and both the power $P_0 = I_{\max} U_0$ and voltage U_0 to maintain the stationary high-field states of the cycle are much lower than $P_{\max}$ and $U_{\max}$, respectively (in the case of a superconducting magnet P_0 is zero!), it is advantageous to separate the driving networks for the transitions and for the steady states. This concept was first introduced by Redfield et al.,⁵ but in a rather elementary way. Its main advantage comes from the fact that though P_S must be made extremely high (up to

many hundreds of kilowatts) the related average energy $\langle E_S \rangle = P_S t_S$ is still relatively small because of the short switching time, typically of the order of milliseconds. Therefore, it is possible to take this switching energy and voltage from a precharged, sufficiently large high-voltage capacitor, C , which allows the collection and storage of the required energy over the whole cycle period from a comparably small auxiliary electric supply. Such a storage capacitor and suitable switching networks^{6–13} can very effectively provide much higher driving voltages for the field transitions than the main lower-voltage current system, and thus achieve the fast current changes where desired. This is the well known energy storage principle of Redfield.⁵ Since its original application the concept has been extended and refined in such a way that the magnetic energy of the coil is used to charge and recharge the storage capacitor during the field switch-off intervals instead of dissipating it in a damping resistor as in Redfield's work.^{8,10,11} After the initial charging of the capacitor by the auxiliary supply, the switching device transforms magnetic coil energy to electric field energy and vice versa, so that the average additional power needed to generate the fast cycle transitions remains relatively low, typically less than a few percent of the main system. Essentially, only the ohmic losses of the circuits have to be compensated.

3.3 MOSFET–GTO Switching Networks

Figure 4 illustrates the basic components of an advanced fast FC network,^{8–13} using high-voltage field effect transistors (MOSFETs) to regulate the magnet current for the stationary field states, and high-voltage gate turn-off thyristors (GTOs) to control the current paths of the energy storage during the transition periods. These and similar devices reported in the literature operate in general as follows. The current through the magnet coil, from a high-power low-voltage dc supply, is regulated by a MOSFET bank network, which tolerates the high-voltage peaks induced by the current switching of up to more than 1 kV without being damaged. To reduce the magnet current at the end of the polarization period, the gates of the MOSFETs are regulated to a selected level, and thus the decreasing current is partially driven by the storage capacitor, which is precharged by an additional high-voltage, low-current source up to the limits of the components, characteristically 1 kV. This auxiliary supply provides an adjustable voltage for the field transitions, so that the ratio U_C/L responsible for the slope of the current changes can be made considerably larger than the ratio U_0/L determined by the main current source, and consequently the transit from high to low becomes faster by a factor U_C/U_0 . Similarly, to increase the current through the coil from a given lower level, the MOSFET gates are opened again, and simultaneously the high voltage of the storage capacitor is connected with the correct polarity to the coil by firing the GTO thyristor. In this way the current turn-off and turn-on can be driven by the same voltage $U_C \gg U_0$. Finally, as soon as the detection field level is reached, the GTO is switched off and the MOSFETs begin to stabilize the new detection state of the cycle. Figure 4 includes the different current paths for the four individual regulations of the switching network. In the high to low step the device transforms the magnetic coil energy to the electric field energy of the storage capacitor, and in the low to high step the process

Figure 4 Basic components of a fast FC network with energy storage, making use of a MOSFET bank to regulate the current of the main power supply through the magnet coil, and a GTO to control the auxiliary high-voltage supply and the energy storage by the capacitor C. The figure illustrates (a) the basic network and (b) the four individual current paths for the transitions and steady states of the field cycle, timed by a cycle programmer

is inverted. By this means it has become possible to obtain maximum fields of more than 1 T with switching times of approximately 1 ms,^{7–13} i.e. much more powerful and faster cycling instruments are possible than without energy storage. Unfortunately, commercial help for building such FC devices is still rather poor. Improvements to noncommercial switching networks, however, have become more and more facile by the availability of novel and less expensive semiconductor components such as POWER-MOSFET and POWER-IGBT (insulated gate bipolar transistor) packages,^{17,18} which have properties similar to individual field effect transistors, but can handle higher currents without the need to connect an inconveniently large number of them in parallel.

3.4 Magnet Coil Geometries

Many different forms of air-cored coils have been considered and tried for FC spectrometers.^{1,2} Originally, the Helmholtz

ring pair arrangement was highly favored because of the well understood mathematics and the convenient radial access to the center of the magnet. However, the field at this center is markedly weakened relative to the strength near the inner surface of the conductor rings because of the wide air gap. Furthermore, even in the ideal case of negligible conductor cross section relative to the gap area, good homogeneity is confined to a rather small space around the midpoint region, and deviations from the ideal Helmholtz geometry are hard to correct. This circumstance, together with the poorer theoretical B/I ratio compared with cylindrical geometries, has made it evident that Helmholtz-type coils are not a good solution for FC magnets. Cylindrical coils can be designed that are superior to ring pairs with regard to many critical specifications such as maximum flux density, homogeneity, and total field volume, as was pointed out in the historic paper of Hak;¹⁹ this result has long been overlooked. To take advantage of the cylinder geometry, however, one has to accept the inconvenience of having only axial access to the field center, which is why only later developments concentrated on such magnets. The ideal cylinder (solenoid, length $\gg$ diameter) theoretically gives a zero field gradient at its center, yet demands an unreasonable length and field volume, and hence it is necessary to look for short systems with suitable refinements of the field homogeneity. Various practicable ways exist to increase the current density at the ends of short cylindrical coils in order to diminish the field gradient over the central region by modifications to the conductor construction.^{1,2,19–22} The most important of these modifications are shown in Figure 5, and are namely a linearly increasing number of conductor loops (linearly varied winding), a reduced number of loops (or even a gap) in the central part (outer notch), decreasing loop separations toward the coil ends (graduated current density), and conductor loops with a continuously variable cross section (optimized current

Figure 5 Cylindrical air core coil geometries to increase the field homogeneity of short FC magnets with small field volume

Figure 6 Conductor cross-section distribution (upper half) of a 2.4 T/50 kW FC magnet with optimized current density

density). By far the best results have been obtained using the last approach, which makes use of a novel Lagrange formalism²¹ to calculate the most efficient coil and loop geometry under selectable constraints; i.e. it evaluates the conductor distribution that maximizes the field B for a given electric power P by simultaneously observing selectable target points (constraints) on the field homogeneity $B/\Delta B$ and the field volume V , i.e. indirectly on the inductance L . This Lagrange minimization procedure allows an inversion of the Biot–Savart law $[B(I)]$ relationship to a current–field law $[I(B)]$ relationship for conductor segments with an arbitrarily high number of adjustable coil parameters, and so gives an explicit (numeric) solution for the optimized current distribution. Several prototypes of such powerful FC magnets have been fabricated by cutting the calculated conductor rings from suitable copper and aluminum tubes. The cutting was performed either mechanically with isolating gaps as fine as 0.1 mm by means of a computer-controlled turning lathe,^{11,21,22} or with less narrow gaps by computer-controlled spark erosion techniques.¹² Figure 6 represents the conductor cross sections of a 2.4 T/50 kW magnet manufactured in the author's laboratory.²² The coil has 12 layers with about 20 000 parameters and an air bore of 24 mm diameter. The inner windings were cut from copper tubes, and the outer ones from aluminum tubes to lessen cutting problems.

4 REFINEMENT AND EXTENSIONS

FC is a particularly useful technique if the NMR properties to be investigated and the models involved depend on the Larmor frequency ν or the related magnetic energy splittings, and thus allow scaling of other frequencies, reorientation rates, coupling constants, and interaction energies of the spin system. Originally, FC was primarily used to study the frequency or field dependence of relaxation times in liquids, in order to analyze molecular motions by relaxation models; after numerous instrumental improvements, however, the technique can also be applied to quite different aims and problems. Though only relatively few laboratories have

contributed systematically to instrumental developments, there has been a remarkable increase in the number of research groups working with FC, and numerous papers have now been published in this subject area.^{1–16} Results are available for many types of materials, such as pure liquids, diamagnetic and paramagnetic solutions, liquid crystals, biological systems, molecular and ionic crystals, polymers, metals, alloys, and both classical and high-temperature superconductors. A large number of the earlier contributions have been summarized in several reviews^{1–3} about both the technical concepts and physical findings of FC studies. Broadly, one can distinguish four types of applications, which require somewhat different spectrometers for suitable B_0 cycles (Figure 7), rf pulse sequences $B_1(t)$, and data-processing methods. Some of these special FC subjects are described in related articles in this Encyclopedia.

4.1 Relaxation Dispersion

The main intention here is to study atomic or molecular motions by the frequency dependence of spin relaxation times^{1–3} (relaxation spectroscopy, or relaxometry), commonly by $T_1(\nu)$ (longitudinal to B_0 , see Figure 3) and more rarely also by $T_2(\nu)$ (transverse to B_0 , see Figure 7). The interesting combination of FC with other spin relaxation processes such as $T_{1\rho}$ (rotating frame), T_{1d} (dipolar), or T_{1q} (quadrupolar), i.e. with more sophisticated spin preparation rf pulses, is still in its early stages.²³ In recent years, relaxation spectroscopy of solid-type signals has been extended from protons to other less sensitive but weaker coupled nuclei, e.g. deuterons, essentially to allow selective frequency-dependent measurements for different sites on a molecule by means of fast Fourier transform data processing.^{11,24,25} The inclusion of this standard high-field NMR practice in fast electronic FC methods was an old but hard to realize challenge, and the experimental problems for this aim, which requires better magnet stability and homogeneity than previous nonselective work, have not yet been solved satisfactorily. Another fascinating recent development originated from the combination of relaxation spectroscopy with imaging procedures,¹⁶ whereby using very inhomogeneous relaxation fields the T_1 dispersion over a broad range is spatially encoded in the sample; thus with adequate imaging rf pulses it is feasible to determine $T_1(\nu)$ in principle by one single B_R adjustment, i.e. by one single cycle. Obviously, these two refinements need almost opposite magnet specifications.

4.2 Zero Field NMR

In this case the original purpose was to enhance the spectral resolution^{14,15,26} for polycrystalline or powdered samples through the phenomenon that in a zero magnetic field the Zeeman energy, and consequently also the line broadenings caused by the orientational distribution of dipolar or quadrupolar coupling tensors relative to the external Zeeman field B_0 , become irrelevant. In a zero field these interactions are made the dominant energy terms of the spin Hamiltonian, which can entail more favorable transition rules and thus simplify the NMR spectrum.²⁶ Almost all reported measurements were performed by mechanical FC

Figure 7 Advanced forms of B_0 field cycles for (a) angular-dependent NMR measurements, making use of two perpendicular fields B_x , B_z , and (b) zero field, cross relaxation and transverse relaxation studies

instruments^{14,15} and so are restricted to samples with long relaxation times T_1 (≥ 0.1 s), which excludes, for example, biological membranes and liquid crystals. Unfortunately, the few experiments known so far for such samples with short T_1 s (millisecond range) in a zero field have proved rather disappointing,^{27,28} because the expected resolution improvement could not be achieved; it seems to be hidden by the relaxation broadening and by experimental errors.

4.3 Cross-Relaxation Spectroscopy

Relaxation rates often involve a resonant increase in particular Zeeman fields where, as a function of B_0 , different energy levels of the spin system have a crossing point. The advantage of the FC method is to make use of such resonant exchange effects between dipolar, quadrupolar, Zeeman, and other (e.g. vibrational) splittings by properly adjusting the field to the resonance conditions^{29–33} of multiple, different level crossing mechanisms. Using this method it has become

possible to detect directly very small cross couplings between unlike spins or between like spins in different surroundings. These include interactions between protons and quadrupolar deuterons, nitrogens or chlorines,^{2,29,30} between protons and vibrational modes in tunnel systems such as methyl groups,^{9,31} or between quadrupolar spins in a highly symmetric crystal lattice and a less symmetric defect structure.^{13,32,33} In the last case the technique is generally combined with selective irradiation of quadrupole transition frequencies at low fields to enhance the cross-coupling effects (nuclear quadrupole double resonance, NQDR). In addition to relaxation dispersion, several variants of NQRD belong to the most widely used FC applications.¹³

4.4 Angular Dependent FC

Originally, rotations of the field direction were introduced as a means of measuring relaxation times, which are angular dependent relative to special crystal axes,^{2,34} for clearer

model discrimination, as illustrated in Figure 7. Later, the method initiated quite different types of work,^{35–38} where fast electronic field switching is capable of extending considerably the previously used slower alternatives. For example, by changing the magnetic field direction relative to the symmetry axis (director) of liquid crystals, it becomes possible to study the short-time behavior of anisotropic flow processes, particularly the alignment of the director field parallel to B_0 , and thus the many anisotropic viscosities and elastic constants.³⁶ Similarly, one can reduce the dipolar coupling of spins by a fast magic angle orientation of B_0 relative to the director and thus lengthen the effective transverse relaxation time T_2 . In this way, the NMR pulsed field gradient (PFG) diffusion method has been successfully combined with FC for direct measurements of diffusion constants, even those that are angular-dependent, where normal solid-like FIDs are much too short to detect the contribution of the Fick's law signal decay more conventionally.^{37,38}

5 SELECTED EXAMPLES

By far the most extensive applications of FC described in the literature are concerned with biological systems, polymers, and liquid crystals.^{1–3} In these cases the usual NMR approach of determining molecular motions at a constant Larmor frequency by variation of the sample temperature suffers from limitations of the temperature ranges available without changing or degrading the phase of the materials. The following two examples were chosen from the numerous reported results because they required more sophisticated FC techniques than are commonly available.

5.1 Proton Relaxation Dispersion of Water

The mobilities of H_3O^+ and OH^- ions in pure H_2O are known to be considerably greater than those of any other univalent ions. This anomaly is understood to be a consequence of hydrogen bonds between water molecules and the ionic species under the premise that such links facilitate the rapid transfer of protons; for instance, one of the protons of an H_3O^+ ion can jump along the hydrogen bond to combine with an adjacent H_2O molecule faster than without the link. It was recognized by Meiboom as early as 1961³⁹ that the various time constants characteristic for the proton transfer reactions, in particular the mean proton exchange time τ_{ex} of a water molecule, can have a significant effect on the longitudinal and transverse spin relaxation times (T_1 , T_2) of both the hydrogen (1H) and oxygen (^{17}O) atoms (the more abundant isotopes ^{16}O and ^{18}O have no magnetic dipole moment). This additional relaxation rate is essentially due to a scalar magnetic coupling between neighboring 1H and ^{17}O spins, which unlike the normal dipolar 1H – 1H interaction is not averaged by the fast rotational and translational tumbling of H_2O molecules in the liquid state. According to standard relaxation models⁴⁰ the proton exchange statistically modulates the scalar coupling energy and leads to frequency-dependent proton relaxation times T_1 and T_2 at Larmor frequencies ν where $2\pi\nu\tau_{scal} \approx 1$. However, since the natural abundance of ^{17}O is only 0.037%, the dispersion step is extremely small in normal water (only $\approx 25\%$), but it could be observed^{6,41} at low frequencies

Figure 8 Proton spin relaxation dispersion of pure H_2O enriched with 4% ^{17}O (pH 7 and 26 °C) at low Larmor frequencies in the sub-Earth's field range. Lines are model fits^{6,41}

between 100 Hz and 2 kHz, i.e. for Zeeman fields below the Earth's magnetic field. By performing the measurements on ^{17}O -enriched samples, the scalar relaxation contribution is significantly increased, and more powerful FC instruments are needed to observe the full dispersion profiles at low fields. Figure 8 illustrates results for H_2O , enriched with 4% ^{17}O , at room temperature (26 °C) and pH 7. Note that near 100 Hz both T_1 and T_2 become shorter than 10 ms. The solid lines are fits of a two-spin relaxation model⁴⁰ with both dipolar 1H – 1H and scalar 1H – ^{17}O couplings, and yield a correlation time $\tau_{scal} = 2.20$ ms.^{8,41} This is slightly shorter than literature data³⁹ for τ_{ex} , and indicates that the scalar interaction is also affected by mechanisms other than proton exchange, such as the ^{17}O spin relaxation. More details are given in the original papers.^{6,8,41}

5.2 Proton and Deuteron Relaxation Dispersion of Liquid Crystals

Liquid crystalline mesophases have challenged NMR groups with FC equipment since the early 1970s, shortly after theoretical predictions became known that order director fluctuations (ODF, OF), i.e. collective thermal molecular excitations of the long-range orientational order (director field), may play an important role in nuclear spin relaxation. Unique to these materials, which contain rod-like or disk-like, i.e. anisotropic, molecules, it was predicted that such thermal fluctuations of the director should entail rather peculiar T_1 dispersion profiles. In the case of nematic order, they should produce a square root law frequency dependence of the longitudinal spin relaxation time, i.e. $T_1 \sim \nu^{1/2}$, which is a very unusual dispersion behavior^{42,43} for low-viscosity liquids. Since the collective motions are superimposed on noncollective rotational and translational reorientation processes of individual molecules, it took a long time to separate the more common from the characteristic liquid crystalline phenomena. Controversies arose because the range of Larmor frequencies available to conventional spectrometers made the clear distinction of the different superimposed relaxation rates virtually impossible. With the development of fast T_1 FC devices capable of extending measurements of short T_1 s to a regime where the

Figure 9 Proton and deuteron spin relaxation dispersion of nematogen liquid crystals. (a) Comparison of the proton T_1 for PCH-5 in the nematic and isotropic phase. (b) Comparison of the proton and chain deuteron T_1 values for normal and perdeuterated CB-5. Solid lines are model fits^{11,24,25}

square root law dominates other competing terms (note that $T_1 \sim \nu^{1/2}$ gives $1/T_1 \rightarrow \infty$ for $\nu \rightarrow 0$), and which furthermore opened the way for angular-dependent studies under such conditions, a more reliable separation of the significant relaxation processes emerged. The results leave no doubt that the theoretical concept about relaxation by collective molecular fluctuations in liquid crystals at low ν values is basically correct. Figure 9 shows typical T_1 dispersion profiles^{2,11,24,25} for two nematogen liquids: PCH-5 (pentylphenylcyclohexane) and CB-5 (pentylcyanobiphenyl). In both systems $T_1(\nu)$ exhibits at least three different frequency ranges where distinct mechanisms determine the total relaxation rate, in particular the broad square root law profile below the conventional Larmor frequency range. As expected, the $\nu^{1/2}$ contribution vanishes for the isotropic phase of the materials, and in deuterated molecules it is seen for both proton and deuteron spins. This idea allows acceptable theoretical fits^{25,28} (solid lines in Figure 9) to the measured data. However, the detailed analysis of deuteron low-frequency results is only beginning, because

of technical problems involved in selective deuteron FC experiments. The theoretical background of relaxation in liquid crystals and further experiments are discussed in other articles (*Amphiphilic Liquid Crystalline Samples: Nuclear Spin Relaxation*, *Deuteron Relaxation Rates in Liquid Crystalline Samples: Experimental Methods*, and *Liquid Crystalline Samples: Relaxation Mechanisms*).

1 INTRODUCTION

The nuclear magnetic moment is a very sensitive site-specific probe of electronic environment and of dynamics in the gas, liquid, or solid phase. In this article, we specifically consider the nature of the information that can be obtained in the gas phase. Why should one do NMR spectroscopy in the gas phase? In the binary collision limit and in the zero-pressure limit, experimental measurements can be directly connected to quantities that can be calculated from first principles. Gas phase measurements therefore provide direct stringent tests of calculations of molecular electronic properties of the isolated molecule such as the rovibrationally averaged chemical shift, tests of intermolecular shielding surfaces and intermolecular potential surfaces from density and temperature dependence of chemical shifts in the binary collision limit, tests of relaxation theory near the T_1 minimum, and experimental values of cross sections for relaxation, which have a direct connection with the anisotropy of intermolecular potentials. Gas phase NMR measurements also provide cross sections for chemical reactions and intermolecular vibrational energy transfer, which are discussed in *Gas Phase Studies of Chemical Exchange Processes*. The gas phase allows us to do experiments in theoretically tractable systems, then carry over the understanding to the less tractable condensed phase systems where possible.

Variable temperature studies can be carried out in the gas phase, where density is a variable that is independent of temperature. Equivalent experiments in the liquid phase would require high-pressure studies. The ability to work in a regime where only two-body effects are important permits the quantitative characterization of the observations with well-defined quantities such as the second virial coefficient of the chemical shift, which is a direct test of intermolecular shielding surfaces. The linear density region provides collision cross sections for molecular reorientation, or rotational angular momentum transfer, or intermolecular vibrational energy transfer leading to unimolecular reaction. These provide stringent tests of anisotropic intermolecular potentials, distinguishing between

superficially similar potentials, and, in favorable cases, permitting refinement of the best available ones entirely on the basis of gas phase relaxation data. Furthermore, one can extrapolate the measured quantities to the zero-pressure limit to obtain the properties that are characteristic of the nearly isolated molecule, such as chemical shifts and coupling constants, which in turn can be related to intramolecular shielding and J coupling surfaces. At this limit, the intrinsic rate with which an energized molecule in the absence of collisions undergoes a unimolecular reaction such as ring inversion can also be obtained (see *Gas Phase Studies of Chemical Exchange Processes*). A recent review of gas phase NMR studies spanning the density range 10^{16} – 10^{21} molecules cm^{-3} and pressures from under 1 torr to 50 atm provides an overview, including experimental details.¹ In this article, we shall discuss only the intermolecular effects on chemical shifts, the temperature dependence of chemical shifts in nearly isolated molecules, and spin relaxation in the gas phase.

2 INTERMOLECULAR EFFECTS ON CHEMICAL SHIFTS

The nuclear magnetic shielding σ is determined by the electronic distribution around the nucleus of interest. Since interactions between molecules necessarily affect this distribution to some extent, there are observable effects of intermolecular interactions on σ . These intermolecular shifts can be rather large, and are usually observed as gas-to-liquid shifts or solvent shifts, which are difficult to describe quantitatively and interpret theoretically because they are dependent on the structure of the liquid. A table of gas-to-liquid shifts is given in *Chemical Shift Scales on an Absolute Basis*. On the other hand, in a gas of modest density, the nuclear magnetic shielding σ , like other molecular electronic properties, can be expressed in terms of a virial expansion in density ρ :²

$$\sigma(T, \rho) = \sigma_0(T) + \sigma_1(T)\rho + \sigma_2(T)\rho^2 + \cdots \quad (1)$$

Here, the terms dependent on the gas density ρ characterize the intermolecular effects, while the independent molecule value of the shielding, $\sigma_0(T)$, is a function of temperature owing to averaging over intramolecular motions (vibrations and rotations).³ By analogy with the second virial coefficient in the usual expansion for PV/RT , $\sigma_1(T)$ may be called a second virial coefficient of the nuclear shielding. Both $\sigma_0(T)$ and $\sigma_1(T)$ can be obtained from experiments in the gas phase.⁴ In a mixture of gases, $\sigma_1(T)$ due to A–A collisions and $\sigma_1(T)$ due to A–B collisions can be determined separately in a series of experiments. The sign of the intermolecular shielding effects has been found to be uniformly negative,^{3,5}

$$[\sigma(T, \rho) - \sigma_0(T)] < 0 \quad (2)$$

that is, intermolecular effects are deshielding, with only a few exceptions such as the nitrogen shielding in nitriles, pyridine and other similar nuclear sites involving $n \rightarrow \pi^*$ excited states.⁶

2.1 Second Virial Coefficient of Nuclear Shielding

Operationally, $\sigma_1(T)$ is obtained as

$$\sigma_1(T) = -\frac{1}{\nu_0} \lim_{\rho \rightarrow 0} \left(\frac{\partial \nu}{\partial \rho} \right)_T \quad (3)$$

Since the gas phase measurements are not carried out on spherical samples, the measured $\sigma_1(T)$ have to be corrected for the bulk susceptibility, given to a good approximation by $\sigma_{1\text{bulk}} = \frac{2}{3}\pi\chi_{\text{mol}}$ or $-\frac{4}{3}\pi\chi_{\text{mol}}$ for the perpendicular or parallel arrangement of a cylindrical sample in the magnet, where χ_{mol} is the molar magnetic susceptibility of the sample. This is the same for all nuclei in the sample, and is a sizable fraction of the observed apparent $\sigma_1(T)$ for nuclei such as ^1H and ^{13}C , whereas it is a very small fraction for ^{129}Xe . Observed values of σ_1 range from -1×10^{-3} to about -1 ppm amagat $^{-1}$ (1 amagat = 2.687×10^{25} molecules m^{-3} , the density of an ideal gas at 1 atm and 273.16 K). The range of values of σ_1 for a given nucleus not unexpectedly reflects the chemical shift range of the nucleus.³ Xenon-129 in the Xe atom is found to be an ideal probe of intermolecular interactions. Xe intermolecular chemical shifts are very large in comparison with other nuclei.⁷ After correction for bulk susceptibility, typical values of σ_1 at room temperature are^{3,8,9} as shown in Table 1.

A summary of second virial coefficients of shielding for ^{19}F in various molecules has been given by Jameson.¹

2.2 The Intermolecular Shielding Surface

For ^{129}Xe in dilute xenon gas, we can explicitly write $\sigma_1(T)$ in terms of the intermolecular potential function for Xe–Xe interactions and the nuclear shielding function for a Xe atom in a pair of interacting Xe atoms:

$$\sigma_1(T) = \int_0^\infty 4\pi r^2 dr [\sigma(r) - \sigma(\infty)] \exp\left[-\frac{V(r)}{k_B T}\right] \quad (4)$$

where $\sigma(\infty)$ is the nuclear shielding of the isolated Xe atom and $\sigma(r)$ is the shielding of the Xe atom under the influence of a neighboring Xe atom at distance r from it. The expression applies to any pair of rare gas atoms, like or unlike.

A mean field long-range model for $[\sigma(r) - \sigma(\infty)]$ had been advanced by Raynes, Buckingham and Bernstein¹⁰ (RBB) for a molecule in the presence of a neighbor

at distance r and orientations given by θ_1 , θ_2 , ϕ_1 , ϕ_2 :

$$[\sigma(r, \theta_1, \theta_2, \phi_1, \phi_2) - \sigma(\infty)] = \sigma_a + \sigma_E + \sigma_W \quad (5)$$

They include a magnetic anisotropy term σ_a , electrical terms due to permanent electric moments on the neighbor σ_E , and a ‘van der Waals term’ σ_W , the intermolecular contributions to shielding due to dispersion, which was modeled by fluctuating electric fields produced at the molecule by mutual interactions with the neighbor in accordance with the London model of dispersion forces. The latter was taken to be of the form $-B\alpha_2 I_2 r^{-6}$, involving the polarizability and the ionization potential of the neighbor molecule and an empirical parameter B , which was taken to be the same as the average B in the quadratic response of the shielding in a molecule to a uniform static electric field. Later refinements involve the polarizability and ionization potential of the observed molecule as well, for example, $-3B\alpha_2 I_1 I_2 r^{-6}/2(I_1 + I_2)$. This is the only term in the model that applies to a pair of rare gas atoms. However, the magnitude of the average B that has been obtained by ab initio calculations¹¹ for ^{129}Xe in a Xe atom in a static uniform field when used in this model gives a value much too small to account for the observed $\sigma_1(T)$. Therefore, if the model is to be used in this form, the B parameter in it can no longer be identified with the average B in the shielding response to a uniform static electric field. Indeed, when the model is used, the empirical B parameter found in fitting the RBB equation, equation (5), to experiment is at least an order of magnitude larger, because this term in the model makes up for the shielding change due to overlap and exchange—terms that are missing in the long-range model, and which can only be obtained by ab initio calculations on the ‘supermolecule’ (the interacting pair of molecules).

Ab initio calculations of the intermolecular shielding function for ^{39}Ar in the argon atom interacting with another argon have revealed that dispersion contributions are not as important as was originally thought, and constitute only a minor correction when second-order correlation effects on shielding are included in the supermolecule calculation,¹² despite the nearly r^{-6} dependence of the shielding function in the region of interest (i.e., those values of r favored by the $\exp[-V(r)/k_B T]$ weighting). Therefore, to the extent that ab initio shielding calculations at the level that includes second-order correlation effects are the basis for the inclusion of dispersion contributions, one may conclude that there are only very small contributions from dispersion in the intermolecular shifts of rare gases. The shape of the intermolecular shielding function for Ar–Ar is shown in Figure 1. This is the same shape as has been found for the shielding of ^{39}Ar in the Ar atom under the influence of Ne, and for ^{21}Ne shielding in the Ne atom in the presence of another Ne atom or a He atom.¹³ It has been found that when this shielding function is scaled up to ^{129}Xe in various Xe–rare gas pairs, it is possible to reproduce quantitatively the $\sigma_1(T)$ observed for ^{129}Xe in pure xenon, and also for Xe with Kr and for Xe with Ar, in their signs, magnitudes, and temperature dependences.¹² The relative magnitudes of the temperature dependences in these three systems are also reproduced.

Table 1 Second Virial Coefficients of Nuclear Shielding

	$-\sigma_1(\text{ppm amagat}^{-1})$
^1H	0.0003–0.008
^{11}B	0.0085 (in BF_3)
^{13}C	0.0022–0.0105
^{15}N	0.0026–0.04
^{19}F	0.006–0.05
^{31}P	0.0023–0.266
^{77}Se	0.007 (in SeF_6)
^{83}Kr	0.131
^{125}Te	0.01 (in TeF_6)
^{129}Xe	0.166–0.75

Figure 1 Intermolecular shielding function for ^{39}Ar in Ar-Ar obtained from ab initio calculations. Adapted from Jameson and de Dios¹² by permission. The values denoted by ■ include second-order correlation contributions, all other values are from a coupled Hartree-Fock calculation, using the local origins method described in the article *Chemical Shift Calculations by the LORG & SOLO Approaches*

2.3 The Nuclear Site Effect

Intermolecular shieldings are different for different nuclear sites in a molecule under the influence of a solvent molecule. In averaging over all the orientations of the molecule bearing the observed nuclei, the peripheral nuclei suffer larger intermolecular effects than nuclei located in the interior. That is why relatively protected nuclei such as ^{77}Se in SeF_6 or ^{125}Te in TeF_6 have fairly small intermolecular shifts compared with ^{77}Se in H_2Se or ^{125}Te in H_2Te . A direct comparison is possible when the nuclei are the same type and in the same molecule, such as the two N nuclei in the NNO molecule or the three different ^{19}F nuclei in $\text{F}_2\text{C}=\text{CFH}$. A simple model by Rummens et al.¹⁴ depends on the averaging of r_{NS}^{-6} distances between nucleus N and solvent S, while the isotropic intermolecular potential is expressed in terms of the separation R_{CS} between the center of mass of the molecule and the solvent. The average intermolecular shift can then be expressed in terms of the distance d between the nuclear site and the center of mass of the molecule. The distance d changes systematically for each of the three types of F nuclear sites in $\text{F}_2\text{C}=\text{CFX}$, where X varies as H, F, Cl, Br, and I. It has been demonstrated that in this series of molecules, this model provides semiquantitative agreement with experiment in the pure gases; the $\sigma_1(T)$ for the three different ^{19}F nuclei vary with the respective values of d for the nuclear site as expected.¹⁵ Similarly, in the NNO molecule, the end nitrogen

nucleus has a larger intermolecular shift in pure NNO, and in NNO-rare gas, and NNO- SF_6 mixtures.

2.4 Intermolecular Contact Shifts

The ^{129}Xe chemical shifts for Xe in the paramagnetic gases O_2 and NO exhibit a linear dependence on the density of O_2 (or NO) with unusually large slopes.^{16,17} There is, of course, the bulk susceptibility contribution to the apparent $\sigma_1(T)$, but this can easily be corrected for, using

$$\chi_{\text{mol}} = N_{\text{Avo}} \langle \mu_{\text{eff}}^2 \rangle / 3k_{\text{B}}T \quad (6)$$

where $\langle \mu_{\text{eff}}^2 \rangle$ is a very nearly temperature-independent 8 Bohr magnetons for O_2 and a strongly temperature dependent average value for NO. In addition to this bulk susceptibility contribution, there is a strongly temperature-dependent true $\sigma_1(T)$, which has a very different behavior from that in the ^{129}Xe $\sigma_1(T)$ for Xe in Ar, for example. This $\sigma_1(T)$ includes, in addition to the usual intermolecular shielding contribution, a contact shift that arises from the finite electron spin density ρ_{spin} at the ^{129}Xe nucleus from the interaction of the Xe with O_2 or NO, which Buckingham and Kollman¹⁸ attributed to the overlap of the $\text{O}_2(\pi_g^*)$ or $\text{NO}(\pi^*)$ orbitals with the Xe(5s). That is,

$$\sigma_1(\text{contact}) = -\frac{4}{3}\pi \frac{\langle \mu_{\text{eff}}^2 \rangle}{3k_{\text{B}}T} \int_0^\infty 4\pi r^2 dr \rho_{\text{spin}} \exp\left[-\frac{V(r)}{k_{\text{B}}T}\right] \quad (7)$$

It was found that if the normal ^{129}Xe $\sigma_1(T)$ for Xe in hypothetically diamagnetic O_2 or NO were taken to be the same as the observed ^{129}Xe $\sigma_1(T)$ for Xe in Ar and the distance dependence of the shielding change due to contact shift were similar to that of the $\sigma(r)$ for ^{129}Xe in Ar, then the limiting temperature dependence of the contact shift could be extracted. The latter is found to be $1/T$ at the lower temperatures, just as the Curie law behavior predicts, and the magnitude of the intermolecular contact shielding is roughly three times that of the ^{129}Xe $\sigma(r)$ for Xe in Ar. The integrals shown above can be extracted empirically from the observed density and temperature dependence of the shifts, and are found to have a ratio 1.25 for NO/ O_2 , which agrees with the ratio calculated by Buckingham and Kollman.

2.5 Many Body Terms

The dependence on density becomes nonlinear as the densities approach liquid densities.¹⁹ The intermolecular shielding contributions from the many body terms are found to be opposite in sign to the two-body second virial coefficient of shielding that is found in the dilute gas.¹ That is, the effective density coefficient of shielding for liquids is smaller in magnitude than the σ_1 obtained in the dilute gas. Both are deshielding (excepting the cases of nitrile or pyridine nitrogen nuclei already mentioned), but liquids are less deshielded than one might expect from direct extrapolation to liquid densities. The gas-to-liquid shift thus gives an estimate of σ_1 that is somewhat too small in magnitude, but nevertheless provides a reasonable estimate of σ_1 when density dependence measurements cannot be carried out. The general shape of ab initio intermolecular shielding surfaces and assumption of

largely pairwise-additive shielding contributions are found to be consistent with the signs and general magnitudes of gas-to-liquid and gas-to-solution shifts and adsorption shifts.²⁰ A favorable example is the set of chemical shifts and their temperature dependence in Xe, Xe₂, Xe₃, . . . , Xe₈ clusters trapped in zeolite NaA, which have been reproduced by using grand canonical Monte Carlo averaging of ¹²⁹Xe shieldings assuming pairwise additive isotropic shieldings based on ab initio shielding functions in rare gas pairs.²¹

3 TEMPERATURE DEPENDENCE OF NUCLEAR SHIELDING IN THE ISOLATED MOLECULE

After extrapolation to zero density, there should be no remaining temperature dependence in the case of xenon. However, it was discovered during measurements of σ_1 that the zero-density intercept of the chemical shift changed with temperature when the molecule bearing the nucleus had internal degrees of freedom, and dramatically so for ¹⁹F nuclei.⁴ In practice, the temperature dependence in the limit of zero density is not obtained from the intercepts; rather, the $\sigma_1(T)$ function is fully characterized experimentally from the density dependence of the chemical shift in several samples and then $\sigma_1(T)\rho$ is subtracted from every data point to correct each to the zero-density limit, thereby obtaining [$\sigma_0(T) - \sigma_0(300\text{ K})$]. The general shape of these functions is that the nucleus becomes more deshielded with increasing temperature, usually with a nonlinear temperature dependence, although in the cases of ¹³C in CO and ¹⁵N in N₂ the function is a linear one.²² The magnitude of the temperature coefficient depends on the nucleus—larger for ³¹P and ¹⁹F than for ¹³C. Some examples are shown in Table 2. There is some evidence that the temperature coefficient is very large for transition metal nuclei, although these have been studied in solution rather

than in the limit of zero-density gas. For a given nucleus, the temperature coefficient correlates with the shielding, and is larger for less shielded environments.

The temperature dependence of the shielding results from the same rotational and vibrational averaging that is responsible for isotope shifts. In the context of the Born–Oppenheimer approximation, the separation of the electronic from the nuclear motion allows an intramolecular potential surface to be defined, which is then used in finding the vibrational states and functions. In the same context, the nuclear shielding surface is defined: this is a mathematical surface containing the values of the shielding as a function of the positions of the nuclei in the molecule. Some examples of shielding surfaces are given in *Isotope Effects on Chemical Shifts and Coupling Constants*. The entire shielding tensor changes with the molecular internal geometry, but only the isotropic average about all orientations of the molecule with respect to the external magnetic field concerns us in the gas phase. Thus, the isotropic shielding surface can be described in terms of an expansion of the shielding in powers of the nuclear displacement coordinates such as bond stretches and bond angle deformations and the derivatives of the shielding with respect to these stretches and deformations:

$$\begin{aligned} \sigma(F_1) = & \sigma_e + \left(\frac{\partial\sigma}{\partial r_1}\right)_e \Delta r_1 + \left(\frac{\partial\sigma}{\partial r_2}\right)_e \Delta r_2 \\ & + \sum_{i=3}^6 \left(\frac{\partial\sigma}{\partial r_i}\right)_e \Delta r_i + \left(\frac{\partial^2\sigma}{\partial r_1^2}\right)_e (\Delta r_1)^2 + \left(\frac{\partial^2\sigma}{\partial r_2^2}\right)_e (\Delta r_2)^2 \\ & + \sum_{i=3}^6 \left(\frac{\partial^2\sigma}{\partial r_i^2}\right)_e (\Delta r_i)^2 + \left(\frac{\partial^2\sigma}{\partial \alpha_{12} \partial r_1}\right)_e \Delta r_1 \Delta \alpha_{12} + \dots \quad (8) \end{aligned}$$

for ¹⁹F in an MF₆ molecule, for example. The thermal average of σ then gives $\sigma_0(T)$. The thermal averages of the nuclear displacement coordinates can be obtained if the intramolecular force field is available, as they are for SF₆, for example. In *Isotope Effects on Chemical Shifts and Coupling Constants*, it is shown how these averages are

Table 2 Temperature Coefficients of the Shielding for Molecules in the Zero-Pressure Limit at 300 K

obtained in general. Given the ab initio surface, or the shielding derivatives, and the intramolecular force field, the $\sigma_0(T)$ can be calculated and compared with experiment. It is generally not possible to obtain accurate derivatives of shielding directly from the experimentally observed $\sigma_0(T) - \sigma_0(300\text{ K})$ functions even using very accurate force fields, since the nature of the experimental data allows typically only one, at most two, parameters to be determined empirically. The empirical shielding derivatives that have been estimated from the temperature dependence of the shielding of ^{19}F have made use of the assumption that the bond extension terms completely dominate the shielding. In this way, estimates of the shielding derivatives in the fluoromethanes, fluoroethenes, and MF_6 type molecules have been made. The observed temperature coefficients $d\sigma_0(T)/dT$ for a series of related compounds such as for ^{19}F in substituted fluoromethanes, and generally for ^{19}F in binary fluorides, correlate with the ^{19}F chemical shifts in these compounds, and the least shielded environments show the largest temperature coefficients. The correlation is even better with the paramagnetic part of the shielding.⁹ Although the derivatives in these particular molecules have not been provided by ab initio calculations, it has been found that, for a large number of molecules, the ab initio shielding derivatives for ^{19}F generally correlate with the shielding itself.^{20,23} In the case of F_2 , the shielding derivative estimated from the temperature dependence appears to be too large compared with the ab initio calculations. In N_2 and CO , the shielding first derivatives estimated from the temperature dependences of the ^{15}N and ^{13}C nuclei, respectively, are roughly the same as those calculated from the ab initio surfaces for these molecules.

4 SPIN RELAXATION IN THE GAS PHASE

Spin relaxation in the gas phase provides qualitatively different information from that in the liquid phase. Since the intermolecular dynamics in the gas phase can be modeled more accurately, the gas phase provides critical tests of relaxation theories, allows quantitative separation of two or more contributing mechanisms, and provides a direct connection with the anisotropy of intermolecular potentials.

4.1 Theoretical Treatments of Relaxation and the Connection with Intermolecular Potentials

NMR studies of spin relaxation in molecular gases provide a very sensitive probe of the anisotropic part of the intermolecular potential surfaces. As a function of gas density ρ , the spin-lattice relaxation time T_1 is long at low densities, for which the collision frequency is very low, passes through a characteristic minimum corresponding to a matching between the collision and spin precession frequencies, and then passes into a regime in which it increases linearly with gas density, the so-called ‘extreme narrowing’ regime. As the density increases, there is a less efficient communication through the weak intermolecular coupling between the rotational degrees of freedom (the ‘lattice’) and the nuclear spin system of the effects of reorienting molecular collisions to the nuclear spins. The region of the T_1 minimum permits a measurement of the

strength of the interaction that couples the nuclear spin system to the lattice degrees of freedom. Bloch’s phenomenological equations (**Relaxation: An Introduction**) provide a description of nuclear magnetic relaxation in gas phase systems. In order to make the connection with intermolecular potential energy surfaces, it is necessary to express the relaxation times T_1 and T_2 in Bloch’s equations in terms of quantities that may be directly calculated once an intermolecular potential energy surface has been specified. There are several approaches: the traditional one is to apply correlation function theory to a master equation. This is the approach used by Abragam²⁴ and by Bloom and Oppenheim.^{25,26} Another approach is to employ the kinetic theory of gases in the context of a generalized Boltzmann equation.²⁷ It has been demonstrated by McCourt et al.^{28,29} that the most useful features of each method can be retained in a unified theory by utilizing a projection operator formalism to obtain a memory equation for that part of the distribution function density matrix characterizing the gaseous system and proportional to the nuclear spin operator $\hat{I}$. The memory equation thus obtained is utilized to obtain an integral equation governing the time dependence of the nonequilibrium part of the nuclear magnetization in terms of a kernel having the form of an autocorrelation function.

In the single relaxation time approximation (SRTA), a common correlation time is assumed for all the rotational levels. A multiple relaxation time approximation (MRTA) uses a distribution of correlation times, and has been shown to be necessary in the accurate analysis of the proton relaxation in HCl and in NH_3 molecules in the range of densities including the T_1 minimum, which then provides spin rotation tensor elements that are in excellent agreement with molecular beam values.³⁰ General multilevel expressions for the contributions to the nuclear magnetic relaxation from spin rotation, dipolar, intramolecular, and quadrupolar mechanisms have been given independently by Gordon^{31,32} and by McCourt²⁹ which we shall illustrate here using the example of the D_2 molecule, since it includes three major relaxation mechanisms: spin-rotation, intramolecular dipolar, and quadrupolar mechanisms.

The relaxation of nuclei of rare gas atoms is strictly intermolecular.³³ Although both intermolecular and intramolecular relaxation mechanisms contribute in general to the relaxation of nuclei in molecular gases, intramolecular relaxation dominates by five or so orders of magnitude (excepting the intermolecular relaxation due to a paramagnetic collision partner, which we shall consider later). It is also typical of the molecular gases that have been studied that shielding anisotropy and scalar coupling mechanisms are not important. We shall also only show here the theoretical expressions (following McCourt^{29,34,35}) appropriate to the *linear density regime* (extreme narrowing conditions), which provide the connection with the anisotropy of intermolecular potential surfaces. This regime is characterized by T_1/ρ . In H_2 , only the spin rotation and dipolar mechanisms, and in D_2 , spin-rotation, dipolar and quadrupolar mechanisms have to be considered. For H_2 , only the *ortho* modification has a nonzero total nuclear spin, whereas in D_2 , *para* and *ortho* modifications have to be considered separately:

$$\left(\frac{\rho}{T_1}\right)_{\text{lin}} = \left(\frac{\rho}{T_1}\right)_{\text{lin,sr}} + \left(\frac{\rho}{T_1}\right)_{\text{lin,dq}} \quad (9)$$

The expressions for $\text{H}_2(\text{ortho})$ are

$$\left(\frac{\rho}{T_1}\right)_{\text{lin,sr}} = \frac{2}{3} \frac{(\omega_{\text{sr}}^{\text{H}})^2}{L_0 \langle v \rangle} \mathbf{d}^{(1)\text{T}} \cdot \langle \sigma_v \rangle^{-1} \cdot \mathbf{P} \cdot \mathbf{d}^{(1)} \quad (10)$$

$$\left(\frac{\rho}{T_1}\right)_{\text{lin,d}} = \frac{(\omega_d^H)^2}{L_0 \langle v \rangle} \mathbf{d}^{(2)T} \cdot \langle \sigma_T \rangle^{-1} \cdot \mathbf{P} \cdot \mathbf{d}^{(2)} \quad (11)$$

whereas for the D_2 molecule,

$$\left(\frac{\rho}{T_1}\right)_{\text{lin,sr}} = \frac{2}{3} \frac{(\omega_{sr}^D)^2}{L_0 \langle v \rangle} \mathbf{d}^{(1)T} \cdot \langle \sigma_v \rangle^{-1} \cdot \mathbf{P} \cdot \mathbf{d}^{(1)} \quad (12)$$

$$\left(\frac{\rho}{T_1}\right)_{\text{lin,dq}} = \frac{(\omega_{dq}^D)^2}{L_0 \langle v \rangle} \mathbf{d}^{(2)T} \cdot \langle \sigma_T \rangle^{-1} \cdot \mathbf{P} \cdot \mathbf{d}^{(2)} \quad (13)$$

The gas density ρ is measured in amagats, $L_0 = 2.687 \times 10^{25}$ molecules m^{-3} , the number density corresponding to 1 amagat, $\langle v \rangle$ is the mean relative velocity $(8k_B T / \pi \mu)^{1/2}$, with μ the reduced mass of the colliding pair. The other quantities are described below. The intramolecular spin-rotation and dipolar frequencies come from the intramolecular interaction Hamiltonian in terms of first- and second-rank irreducible tensors:

$$\hat{\mathcal{H}} = -\hbar \omega_{sr}^D \hat{\mathbf{I}} \cdot \hat{\mathbf{J}} + \hbar \omega_d^D \hat{\mathbf{I}}_2 : \hat{\mathbf{u}}\hat{\mathbf{u}} - \hbar \omega_q^D (\hat{\mathbf{I}}_1 \hat{\mathbf{I}}_1 + \hat{\mathbf{I}}_2 \hat{\mathbf{I}}_2) : \hat{\mathbf{u}}\hat{\mathbf{u}} \quad (14)$$

The off-diagonal matrix elements of $\hat{\mathbf{u}}\hat{\mathbf{u}}$ lead to high-frequency effects in NMR,^{26,29,36} which will only affect the NMR relaxation process at densities in which the collision frequencies are comparable to any of the rotational frequencies, at which densities the O and S branches of the Raman spectrum are sufficiently collisionally broadened to overlap with the Q branch. This is usually the case in liquids. For H_2 , such an overlap does not occur even up to densities of 1000 amagat. For dilute gases, the high-frequency terms arising from the off-diagonal matrix elements of $\hat{\mathbf{u}}\hat{\mathbf{u}}$ do not play a significant role in the relaxation; thus, only the diagonal part of $\hat{\mathbf{u}}\hat{\mathbf{u}}$ is taken into account:

$$\begin{aligned} \hat{\mathcal{H}} = & -\hbar \omega_{sr}^D \hat{\mathbf{I}} \cdot \hat{\mathbf{J}} + \frac{\hbar \omega_d^D \hat{\mathbf{I}}_2 : \hat{\mathbf{J}}\hat{\mathbf{J}}}{(4J^2 - 3)} \\ & - \frac{\hbar \omega_q^D (\hat{\mathbf{I}}_1 \hat{\mathbf{I}}_1 + \hat{\mathbf{I}}_2 \hat{\mathbf{I}}_2) : \hat{\mathbf{J}}\hat{\mathbf{J}}}{4J^2 - 3} \end{aligned} \quad (15)$$

It has been shown that the last two terms give the combined dipolar/quadrupolar coupling Hamiltonian in terms of the total spin $\hat{\mathbf{I}}$, $-\hbar \omega_{dq}^D \hat{\mathbf{I}} : \hat{\mathbf{J}}\hat{\mathbf{J}} / (4J^2 - 3)$ in which

$$\omega_{dq}^D(\text{para}) = 2\omega_d^D - \frac{3}{2}\omega_q^D \quad (16)$$

$$\omega_{dq}^D(\text{ortho}) = \frac{12}{5}(\omega_d^D)^2 - \frac{6}{5}\omega_d^D \omega_q^D + \frac{9}{4}(\omega_q^D)^2 \quad (17)$$

The matrices $\langle \sigma_v \rangle$ and $\langle \sigma_T \rangle$ contain the state-to-state reorientation effective collision cross sections, averaged over a Boltzmann distribution of translational energies, associated with the irreducible first-rank tensor operator $\hat{\mathbf{J}}$ and the second-rank irreducible tensor operator $\hat{\mathbf{J}}\hat{\mathbf{J}} / (4J^2 - 3)$ respectively. The population matrix $\mathbf{P}$ is diagonal, with the j th element being the fractional population per state associated with the j th rotational manifold, $e^{-E_j/k_B T} / \sum_j (2j+1)e^{-E_j/k_B T}$, while $\mathbf{d}^{(1)}$ and $\mathbf{d}^{(2)}$ are vectors whose j th elements are the reduced matrix elements of $\hat{\mathbf{J}}$ and $\hat{\mathbf{J}}\hat{\mathbf{J}} / (4J^2 - 3)$ respectively, in the Edmonds convention:

$$d_j^{(1)} = \langle j | \hat{\mathbf{J}} | j \rangle = [j(j+1)(2j+1)]^{1/2} \quad (18)$$

$$\begin{aligned} d_j^{(2)} &= \langle j | \hat{\mathbf{J}}\hat{\mathbf{J}} / (4J^2 - 3) | j \rangle \\ &= \frac{[j(j+1)(2j+1)]^{1/2}}{[6(2j-1)(2j+3)]^{1/2}} \end{aligned} \quad (19)$$

These are equivalent to the equations derived by Gordon.^{32,36} The correspondence with Gordon's notation is shown by Lemaire et al.³⁵ The cross-relaxation terms only become important at pressures below the T_1 minimum. Furthermore, with the *ortho* relaxing at least three times more slowly than the *para* D_2 and being favored in the 5:1 equilibrium ratio of these two modifications, only the relaxation of the *ortho* D_2 is observed experimentally. The equations for the relaxation behavior of D_2 are also applicable to $^{14}\text{N}_2$; however, for ^{14}N , the quadrupolar interaction dominates to the extent that the other nuclear spin interactions can be totally ignored, so that the relaxation rates for *ortho* and *para* modifications of N_2 are equal.

It has been demonstrated that the $(T_1/\rho)_{\text{lin}}$ data of H_2 and its isotopomers at infinite dilution in a rare gas are capable of distinguishing between the various proposed potential surfaces of H_2 -rare gas (He, Ne, Ar).^{34,35,37-39} Potential energy surfaces did not differ significantly in their ability to reproduce various experimental quantities such as virial coefficients, molecular beam scattering, transport properties and their field effects, and yet provide different results for T_1/ρ versus temperature data. The sensitivity of the computed spin relaxation times to different parts of the H_2 -He potential has been examined in detail.⁴⁰ Both types of cross sections obtained from relaxation data in dilute gas are very sensitive to both the isotropic part of the potential and the $P_2(\cos \theta)$ terms, and sensitive to the $P_4(\cos \theta)$ terms, but less sensitive to higher orders. In a further example, the ^{15}N and ^{14}N spin relaxation data for N_2 in Ar have been used to distinguish between potential surfaces and to refine the best available one.⁴¹ While quantum scattering calculations are essential for the hydrogen case, it has been shown that classical trajectory calculations are quite reliable for the case of the nitrogen molecule.

In the single relaxation time approximation (SRTA), in the extreme narrowing limit, $\mathbf{d}^{(1)T} \cdot \langle \sigma_v \rangle^{-1} \cdot \mathbf{P} \cdot \mathbf{d}^{(1)}$ becomes $\langle j(j+1) \rangle / \sigma_J$, where σ_J [or $\mathfrak{S}'(01)$ in the literature on kinetic theory of polyatomic gases²⁹] is a density-independent cross section for spin-rotation relaxation. In the same limit, $\mathbf{d}^{(2)T} \cdot \langle \sigma_T \rangle^{-1} \cdot \mathbf{P} \cdot \mathbf{d}^{(2)}$ becomes $\frac{1}{6} \langle j(j+1)/(2j-1)(2j+3) \rangle / \sigma_{\theta,2}$, where $\sigma_{\theta,2}$ [or $\mathfrak{S}'(02)$ in the kinetic theory literature] is a density-independent cross section for molecular reorientation, the cross section associated with both dipolar and quadrupolar relaxation. This cross section differs from that for depolarized Rayleigh light scattering, σ_{DPR} (or $\mathfrak{S}_{\text{DPR}}$), only in that the latter includes contributions from a rotating collision partner, which means that $\sigma_{\theta,2}$ and σ_{DPR} are identical when the collision partner is a rare gas atom. Therefore, for a linear molecule,

$$\left(\frac{\rho}{T_1}\right)_{\text{lin,sr}} = \frac{2}{3} \frac{(\omega_{sr})^2}{L_0 \langle v \rangle \sigma_J} \langle j(j+1) \rangle \quad (20)$$

In the 'high-temperature' or classical limit, $\langle j(j+1) \rangle = 2I_0 k_B T$ for linear molecules, where I_0 is the molecular moment of inertia. For homonuclear dipolar relaxation,

$$\left(\frac{\rho}{T_1}\right)_{\text{lin,d}} = \frac{4}{3} I_2 (I_2 + 1) \frac{(\omega_d)^2}{L_0 \langle v \rangle \sigma_{\theta,2}} \frac{1}{6} \left\langle \frac{j(j+1)}{(2j-1)(2j+3)} \right\rangle \quad (21)$$

For a quadrupolar nucleus, when the dipolar and the cross relaxation between dipolar and quadrupolar are negligible compared with the quadrupolar relaxation rate,

$$\left(\frac{\rho}{T_1}\right)_{\text{lin,q}} = \frac{(\omega_q)^2}{L_0 \langle v \rangle \sigma_{\theta,2}} \frac{1}{6} \left\langle \frac{j(j+1)}{(2j-1)(2j+3)} \right\rangle \quad (22)$$

The average $\langle j(j+1)/(2j-1)(2j+3) \rangle$ goes to $\frac{1}{4}$ at the high-temperature limit, so that the above relationships, using the definitions of ω_d and ω_q , become the familiar

$$\left(\frac{\rho}{T_1}\right)_{\text{lin,d}} = \frac{1}{2} I_2(I_2+1) \frac{\gamma^4 \hbar^2 (r^{-3})^2}{L_0 \langle v \rangle \sigma_{\theta,2}} \quad (23)$$

$$\left(\frac{\rho}{T_1}\right)_{\text{lin,q}} = \frac{3}{160} \frac{2I_1+3}{I_1^2(2I_1-1)} \frac{(eqQ/\hbar)^2}{L_0 \langle v \rangle \sigma_{\theta,2}} \quad (24)$$

which were first derived by Gordon.⁴²

In a dilute gas, the concept of a correlation time τ is physically obvious. Since a collision is itself a very short time event, the correlation time, the time it takes for a molecule to lose memory of the orientation of its angular momentum vector, is just the average time between those collisions that change the orientation of the rotational angular momentum vector:

$$\tau_J = [\rho \langle v \rangle \sigma_J]^{-1} \quad \text{or} \quad \tau_2 = [\rho \langle v \rangle \sigma_{\theta,2}]^{-1} \quad (25)$$

where σ_J and $\sigma_{\theta,2}$ are the effective cross sections for collisions that change the rotational angular momentum vector or its orientation, defined explicitly above, and can be calculated by quantum scattering or classical trajectories. The conventional definition of correlation time $\tau_{\theta,2}$ (as most often used in the liquid phase) is thus $\frac{1}{4}\tau_2$ for dipolar and quadrupolar relaxation in linear molecules in a dilute gas.^{29,43,44}

Between collisions, the molecule is rotating freely. The spin-rotation interaction is not affected by the precession of the molecular symmetry axis about $\mathbf{J}$ between collisions. On the other hand, in dipolar relaxation, since the spin precession in the magnetic field is slow compared with molecular rotation frequencies, only the conserved or rotationally averaged component of the intramolecular dipolar magnetic field, modulated by collisions, contributes to the spin relaxation.⁴³ For nuclei with electric quadrupole moments, the relaxation depends on the coupling to the conserved part of the electric field gradient tensor, modulated by collisions. The averaging of second-rank tensor types of interactions leads to a factor of $\frac{1}{4}$ for linear molecules and $\frac{1}{5}$ for tetrahedral spherical tops. Similarly the symmetry axis of a symmetric top molecule precesses many times about $\mathbf{J}$ between collisions, thus resulting in an averaging of the spin-lattice interaction for a tensor of rank 2 by an amount $P_2(\cos \theta_0)$, where θ_0 is the angle that the dipolar axis or the electric field gradient symmetry axis makes with the molecular symmetry axis. These important and dramatic geometrical effects on the T_1/ρ values for the D spins in CD₃H, CD₂H₂, CDH₃, and CD₄ have been observed.²⁶ Such geometrical effects arising from averaging of the interaction during the free rotation between collisions in the gas phase do not apply to the spin-rotation mechanism, as mentioned above, so the proton relaxations in these systems have only the very small differences associated with the variation of $\langle j(j+1) \rangle$ with rotational constants.

In the language of correlation functions, Bloom et al.²⁶ emphasized the physical origin of this factor of $\frac{1}{4}$ by writing the correlation time as $f_2 \tau_2$, where f_2 has a different numerical value for molecules of different geometry or for different nuclear sites in the same molecule. In the language of correlation functions,

$$\tau_{\theta,2} = \int_0^\infty g(t) dt, \quad \text{where} \quad g(t) = [g(t)]_{\text{free rot}} [g(t)]_{\text{coll}} \quad (26)$$

$$\tau_2 = \int_0^\infty [g(t)]_{\text{coll}} dt, \quad f_2 = \int_0^\infty [g(t)]_{\text{free rot}} dt \quad (27)$$

where the oscillatory nature of the correlation function for the free rotation between collisions gives rise to the factor $f_2 = \frac{1}{4}$ for linear molecules and $\frac{1}{5}$ for tetrahedral spherical tops. For a given collision pair, for example, CH₃D-Ar, the geometrical effects on ¹H or D relaxation are different; nevertheless, the cross section $\sigma_{\theta,2}$, which is a property of the CH₃D molecule with Ar, should be the same whether derived from ¹H or D spin relaxation.

4.2 Analysis of T_1 Measurements

A review of T_1 studies in the gas phase by Armstrong⁴⁵ provides some interesting examples in the region of the T_1 minimum. The effects of centrifugal distortion can be incorporated into the T_1 expression, as was found to be necessary in the interpretation of the low-density data for proton relaxation in CH₄ and SiH₄. In the region of the T_1 minimum, the assumption of a single relaxation time for all rotational levels (SRTA) gives a poorer fit to experimental data than multiple relaxation times (MRTA). In some cases, it is found that a distribution of correlation times τ_J leads to a better fit to the data and to a more accurate spin-rotation tensor from the T_1 minimum. Beyond the T_1 minimum, T_1/ρ should be a constant independent of ρ for a given temperature. However, in some cases, dimers formed by van der Waals interactions can result in contributions to the relaxation by the rotational states of the observed molecule, as was found in H₂-Ar.³⁹ This leads to a maximum in the T_1/ρ versus ρ curve, which can be fitted theoretically by considering the dynamics of formation and annihilation of the dimers.

Separate relaxation of nuclei in magnetically inequivalent sites has been measured in SF₄ and in NNO. The former was carried out in the region of the T_1 minimum. The different relaxation rates are characteristic of the different paramagnetic shieldings at the two sites, which have known relationships to the respective spin-rotation tensors.⁴⁶ When measurements are made beyond the T_1 minimum in two or more nuclear sites in the molecule, the same σ_J and $\sigma_{\theta,2}$ cross sections (which are characteristic of the molecule and independent of which nucleus is observed) should result from the analysis. This was the case for NNO. Similarly, both ¹H and ¹³C provide the same σ_J cross section for CH₄. Relaxation information for more than one nuclear site in the same molecule provides redundancy of information. Cross sections obtained from different isotopomers have different kinematic factors and should be slightly different; scattering calculations have to be carried out for each isotopomer.

In a mixture of two gases, the analysis provides cross sections for the unlike pair of molecules if the pure gas experiment has been done, since the relaxation times in the extreme narrowing limit due to two types of collision partners are additive:⁴²

$$T_1(A) = (T_1/\rho)_{A-A}\rho_A + (T_1/\rho)_{A-B}\rho_B \quad (28)$$

The characteristic $(T_1/\rho)_{A-B}$ provides $\sigma_J(A-B)$ or $\sigma_{\theta,2}(A-B)$.

4.3 Spin–Rotation Relaxation

In most molecules, the nuclear spin angular momentum of the ^{19}F nucleus is coupled to the molecular rotational angular momentum by a rather large spin–rotation constant, so that the ^{19}F nuclear spin is relaxed predominantly by the rotational magnetic fields. In the extreme narrowing regime, in the gas phase,

$$\left(\frac{\rho}{T_1}\right)_{\text{in, sr}} = \frac{2}{3} \frac{(\omega_{\text{sr}})^2}{L_0 \langle \nu \rangle \sigma_J} \langle j(j+1) \rangle \quad (29)$$

where

$$(\omega_{\text{sr}})^2 = C_{\text{eff}}^2 = \left[\frac{1}{3}(C_{\parallel} + 2C_{\perp})\right]^2 + \frac{4}{45}(C_{\parallel} - C_{\perp})^2 \quad (30)$$

involving the spin–rotation tensor components, and $\langle j(j+1) \rangle = 3I_0/k_B T$ for spherical tops such as CF_4 , SiF_4 , SF_6 , SeF_6 , and TeF_6 , whereas for a linear molecule, $C_{\text{eff}}^2 = C_{\perp}^2$ and $\langle j(j+1) \rangle = 2I_0/k_B T$. The assumptions that allow the above T_1 equation to be used are that

1. the Larmor frequency is small compared with the collision frequency;
2. the duration of a collision is short compared with the average time between collisions;
3. the interactions among the collision partners do not significantly influence their collisions with the observed molecule;
4. bound states between the observed molecule and the collision partner have no significant effect on the spin relaxation.

Independent knowledge of the spin–rotation tensors from molecular beam electric or magnetic resonance or high-resolution microwave spectroscopy leads to $\sigma_J(T)$ directly from measurements of T_1 . The temperature dependence of these cross sections appears to be described well enough by a power law:

$$\sigma_J(T) = \sigma_J(300 \text{ K})(T/300 \text{ K})^{-m} \quad (31)$$

These cross sections have been measured in NNO, CO_2 , CO , N_2 , CF_4 , CH_4 , SF_6 , SeF_6 , and TeF_6 molecules in collisions with self, Ar, Kr, Xe, N_2 , CO , CO_2 , HCl , CH_4 , CF_4 , and SF_6 molecules. Cross sections ranged from 0.09 nm^2 for SF_6 in CH_4 to 1.29 nm^2 for TeF_6 in pure TeF_6 at 300 K. The temperature exponent ranged from $m = 0.44$ for ^{13}CO in SF_6 to 1.62 for TeF_6 in SF_6 , not uniformly $m = 1$ as was originally expected. Two $\sigma_J(T)$ sets for one interacting pair help to test the anisotropy of one interaction potential, offering the possibility of probing different parts of the potential surface; for example, $\sigma_J(T)$ of ^{13}CO in N_2 – CO provides the anisotropy around CO , primarily $dV/d\theta_1$, where θ_1 is the angle that the CO molecule makes with the line connecting the

centers of mass of the two molecules, and $\sigma_J(T)$ of $^{15}\text{N}_2$ in N_2 – CO provides the anisotropy around N_2 , primarily $dV/d\theta_2$, where θ_2 is the angle that the N_2 molecule makes with the intermolecular axis. A summary of σ_J cross sections and exponents m has been published.¹

Each cross section is determined uniquely by the nature of interaction of the collision pair. As we have seen, the theoretical formalism provides the means, given the potential energy surface (PES), to calculate directly, via quantum scattering or classical trajectory methods, the observed cross sections. Nevertheless, there are interesting general observations that an examination of these cross sections reveals.⁴⁷

1. Collision efficiencies can be defined in terms of the collision cross section divided by a geometric cross section, to take into account the relative sizes of the molecules. We have been using $(\sigma_J/\pi d_{12}^2)$, where d_{12} is taken from the distance scaling parameter in the conformal isotropic potential functions, the value of r at which $V = 0$. In comparing across the various observed molecules, it appears that the most important factor determining the absolute magnitude of the observed efficiencies of angular momentum change in the target molecule 1 by collision partner 2 is the anisotropy of the electronic distribution of the target molecule. For any given collision partner, the largest efficiencies are observed for the NNO molecule, followed by CO_2 and CO . To an approaching projectile, the anisotropy of the NNO molecule appears the greatest, followed by CO_2 and CO , in that order. The shape of the projectile molecule appears to be of secondary importance. Having corrected for the geometric sizes, projectiles Ar and HCl are observed to have about the same effect as do CF_4 and Xe on a nearly isotropic target such as SF_6 .
2. The collision cross section for any given observed molecule increases with increasing mass (and number of electrons) of the collision partner—not unexpectedly, because of the geometric sizes. Having been corrected for the geometric sizes, the collision efficiencies also increase with increasing mass and number of electrons of the collision partner. Part of this has to do with the kinematic factors, which can be modeled by classical collisions between hard bodies, as in Chandler’s perfectly rough hard spheres model.⁴⁸ The collision efficiency involves a kinematic factor containing only reduced masses and moments of inertia of the form

$$\left\{ \frac{I_0(1)}{\mu_{12}d_{11}^2} + \frac{1}{2} \left[1 + \frac{I_0(1)d_{22}^2}{I_0(2)d_{11}^2} \right] \right\}^{-1} \quad (32)$$

which applies to linear or spherical top target molecules and molecular collision partners (not rare gas atoms). The other part can be attributed to attractive forces increasing roughly with increasing number of electrons of the partner.

3. The observed collision efficiencies of the CH_4 molecule are nearly the same for nearly all partners, with the small mass of CH_4 having a leveling effect, making the reduced mass of the collision pair nearly the same for all partners.
4. Electrical moments of the collision partner enhance collision efficiencies by introducing sizable angle-dependent terms in the intermolecular potential. Thus, collision efficiencies involving HCl as a partner are higher than might be expected for its number of electrons; so do those involving CO_2 and NNO, which have large electric quadrupole moments.
5. Despite the similarities of kinematic factors for NNO with CO_2 or CO with N_2 , there are clear differences in their

Table 3 Thermal Average Cross Sections for Molecular Reorientation, $\sigma_{\theta,2}$ (300 K)⁵¹

Collision partner	$\sigma_{\theta,2}$ (nm ²)			$\sigma_{\theta,2}/\sigma_J$		
	¹⁴ N ₂	¹⁴ NNO	CD ₄	N ₂	NNO	CD ₄
CH ₄ or CD ₄	0.31	0.452	0.391	2.2	1.67	2.1
N ₂	0.293	0.430	0.390	2.0	1.46	2.4
CO	0.32	0.470	0.381	2.1	1.42	2.4
Ar	0.32	0.474	0.354	2.1	1.26	2.5
Kr	0.41	0.656	0.459	2.3	1.18	2.5
HCl	0.36	0.634	0.536	2.0	1.22	2.3
Xe	0.44	0.762	0.520	2.2	1.18	2.3
CO ₂	0.59	0.754	0.599	2.0	1.26	2.5
NNO		0.755			1.27	
CF ₄	0.59	0.798	0.614	2.0	1.11	2.5
SF ₆	0.73	0.994	0.779	1.9	0.96	2.3

cross sections that cannot be accounted for by the very small electric dipole moments in NNO and CO. This is an indication of the sensitivity of the σ_J cross sections to the details of the anisotropy of the intermolecular potential.

6. There is a rough correlation between the magnitude of the temperature exponent of $\sigma_J(T)$ and the well depth ε_{12} for the collision pair. This is consistent with Chandler's model,⁴⁹ in which the collision efficiencies are multiplied by an exponential factor $\exp(\varepsilon_{12}/k_B T)$ to include the effects of attractive forces.

4.4 Quadrupolar Relaxation

The ¹⁴N nucleus in ¹⁴N₂ and the end ¹⁴N nucleus in ¹⁴N¹⁴NO relax entirely by the quadrupolar mechanism, which allows us to characterize quadrupolar relaxation cross sections in the gas phase.^{50,51} On the other hand, the much smaller electric field gradient for the middle nitrogen in NNO leads to a competing spin-rotation and quadrupolar mechanism for this nucleus. Nevertheless, $\sigma_{\theta,2}(T)$ for the ¹⁴N¹⁴NO molecule [and also $\sigma_J(T)$] should be independent of whether the end or the middle nitrogen is used to determine the cross section. Similarly, the D relaxation in CD₄ is a combination of spin-rotation and quadrupolar. Whenever more than one mechanism makes a significant contribution to the relaxation, the separation of the two leads to greater errors in the cross sections.

It has been demonstrated by McCourt and co-workers that $\sigma_J(T)$ and $\sigma_{\theta,2}(T)$ are sensitive to different parts of the anisotropic potential, thus providing independent tests. Classical trajectory calculations for $\sigma_J(T)$ and $\sigma_{\theta,2}(T)$ in the N₂-Ar system have provided agreement with the experimental values, upon refining the PES.⁴¹ $\sigma_{\theta,2}(T)$ is found to be most sensitive to variations in the anisotropy of $r_{\min}$ of the PES, and $\sigma_J(T)$ is found to be fairly sensitive to variations both in the anisotropy of $r_{\min}$ and the angular dependence of the repulsive wall of the PES.

A summary of the results of quadrupolar relaxation in gases is given in Tables 3 and 4. A very interesting result is that for ¹⁴N₂ and ¹⁵N₂, the ratio $\sigma_{\theta,2}/\sigma_J$ is very close to 2.0, with 10 different collision partners (ranging from 1.9 to 2.3, with an average of 2.1) and m_J ranges from 0.6 to 1.0, with an average of 0.74 while $m_{\theta,2}$ ranges from 0.62 to 0.91, with an average of 0.71. On the other hand, the ratio $\sigma_{\theta,2}/\sigma_J$ for NNO is somewhat more variable, ranging from 0.96 to 1.67,

with an average of 1.27, m_J ranges from 0.47 to 1.29, with an average of 0.88, and $m_{\theta,2}$ ranges from 0.66 to 0.95 with an average of 0.80. The relaxation of D in CD₄ and H in CH₄ can also be compared for 10 different collision partners, resulting in $\sigma_{\theta,2}/\sigma_J$ ranging from 2.1 to 2.5 (average 2.4), m_J ranging from 0.79 to 1.06 (average 0.88), and $m_{\theta,2}$ ranging from 0.56 to 0.75 (average 0.64).⁵¹ Of course, the kinematic factors are slightly different for the different isotopomers, and we have already seen that kinematic factors such as moments of inertia and reduced masses play a role. In these examples, classical trajectory calculations will have to be carried out for both isotopomers in order to obtain an accurate $\sigma_{\theta,2}/\sigma_J$ ratio for each isotopomer. Other examples are $\sigma_{\theta,2}/\sigma_J = 1.38$ in pure ClF gas at 295 K⁵² and $\sigma_{\theta,2}/\sigma_J = 1.6$ in pure D₂ at 293 K, increasing to very nearly 2.0 at 171 K,⁵³ and for CF₄ in the pure gas, the ratio is very close to 4.0, with $\sigma_{\theta,2}$ obtained from depolarized light scattering. In general, $\sigma_{\theta,2}/\sigma_J > 1.0$ has been found experimentally. Results of classical trajectory calculations with a variety of PES are generally consistent with $\sigma_{\theta,2}/\sigma_J > 1.0$. In general, $m_J > m_{\theta,2}$ has been found experimentally. The greater temperature dependence of σ_J compared with $\sigma_{\theta,2}$ is consistent with the finding by McCourt et al. that σ_J is fairly sensitive to variations in the angular dependence of the repulsive wall, whereas $\sigma_{\theta,2}$ is not, and the general observations by Gordon that σ_J contains information mainly about the higher j states, and is determined both by changes in the magnitude of the rotational angular momentum

Table 4 Temperature Dependence of Collision Cross Sections for Molecular Reorientation $\sigma_{\theta,2}(T) = \sigma_{\theta,2}(300 \text{ K}) (T/300 \text{ K})^{-m}$

Collision partner	m		
	¹⁴ N ₂	¹⁴ NNO	CD ₄
CH ₄ or CD ₄	0.76	0.79	0.65
N ₂	0.62	0.77	0.60
CO	0.69	0.82	0.58
Ar	0.71	0.73	0.65
Kr	0.70	0.80	0.67
HCl	0.78	0.95	0.59
Xe	0.63	0.77	0.75
CO ₂	0.91	0.93	0.71
NNO		0.85	
CF ₄	0.66	0.69	0.66
SF ₆	0.63	0.66	0.56

and by changes in its direction, whereas $\sigma_{\theta,2}$ are affected strongly by reorientation and only to a minor extent by changes in j .^{32,41}

4.5 Intermolecular Dipole–Dipole Relaxation

In intramolecular relaxation mechanisms such as those discussed above, the interactions involved in the spin relaxation are always present within the molecule of interest; collisions interrupt molecular rotation, and thereby introduce the fluctuations of local magnetic fields or electric field gradient tensors that lead to nuclear spin relaxation. In an intermolecular mechanism, the interaction is ‘on’ only during a collision. By their nature, the dependence of intermolecular mechanisms on density, temperature, and magnetic field are very different from those of intramolecular mechanisms in the gas phase. It has been shown that it is possible to take advantage of such differences to separate the intermolecular mechanisms precisely from the ever-present intramolecular ones.^{54–56}

In the gas phase, nuclear spin relaxation by intermolecular magnetic dipolar coupling is usually not an important mechanism. The exception is when the magnetic dipole on the collision partner is from an electron spin. The presence of the electron spin on the collision partner also generates a scalar intermolecular nuclear spin–electron spin interaction, which is responsible for the observed contact shifts discussed in Section 2.4. However, it has been shown that in the case of ^{129}Xe , this scalar mechanism²⁴ accounts for no more than 0.3% of the observed value of $1/T_1$ for ^{129}Xe in O_2 gas.⁵⁷ Under ideal conditions, the separation of the intermolecular dipolar from the other dominant mechanism (e.g., spin–rotation) has been quantitative, permitting the characterization of the intermolecular dipolar mechanism. This was possible for ^1H in CH_4 , ^{19}F in CF_4 , SiF_4 , SF_6 , SeF_6 , and TeF_6 in oxygen gas.^{54–56} After the spin–rotation contributions (which are proportional to $1/\rho$) were taken out, the remainder of the relaxation rate was found to be proportional to the density of oxygen for all temperatures and all fields. For example, for ^{19}F in mixtures of CF_4 in O_2 , the relaxation rates ranged from 10% DD/90% SR up to 80% DD/20% SR.

There is a magnetic field dependence of the intermolecular dipolar relaxation. The duration of a collision, during which time the CF_4 and O_2 molecules are close enough for the electron spin–nuclear spin dipole interaction to cause nuclear spin transition, lasts for only a tiny fraction (1 part in 10^4) of the Larmor period of the ^{19}F nucleus, but a sizable fraction (0.04–0.2) of the Larmor period of the electron spin at typical fields 1.9–9.4 T. It has been found that a field dependence of the form

$$(1/T_1^{\text{DD}}) = (1/T_1^{\text{DD}})_0 [1 - f(T)\omega_1^{1/2}] \quad (33)$$

is consistent with the experimental data for ^{129}Xe , ^1H in CH_4 , ^{19}F in CF_4 , SiF_4 , SF_6 , SeF_6 , and TeF_6 in oxygen gas,^{54–57} where $(1/T_1^{\text{DD}})_0$ corresponds to the zero-field limit. All these results were in the low-frequency limit; that is, the nuclear spin-bearing molecule suffers several collisions during one Larmor precession, and the duration of a collision is a fraction less than one of a Larmor cycle of the electron spin.

In the extreme narrowing limit, the correlation function approach²⁶ and the quantum mechanical formulation of molecular kinetic theory^{27,33} both lead to

$$(1/T_1^{\text{DD}})_0 = \frac{16}{3} S(S+1) \gamma_I^2 \gamma_S^2 \frac{\hbar^2}{d^2} \left(\frac{\pi\mu}{8k_B T} \right)^{1/2} N_S \cdot F(V/k_B T) \quad (34)$$

where N_S is the number density of S -bearing molecules, d is the characteristic length of the intermolecular interaction, loosely referred to as the molecular diameter, and $(\pi\mu/8k_B T)^{1/2}$ is the reciprocal mean relative velocity $\langle v \rangle^{-1}$. The dependence of the intermolecular dipolar relaxation on the intermolecular PES is contained in $F(V/k_B T)$, which can be viewed as a measure of collision efficiency; i.e., the intermolecular dipolar relaxation rate is proportional to an *effective* collision frequency, which is a factor $F(V/k_B T)$ times that for hard spheres of diameter d at the high translational energy limit. At 300 K, $F(V/k_B T)$ is 2.04, 2.83, 3.16, 2.95, 3.66, and 3.75, respectively, for CH_4 , CF_4 , SiF_4 , SF_6 , SeF_6 , and TeF_6 with O_2 , and the temperature dependence is as $T^{-0.4}$. These $F(V/k_B T)$ functions are expected to serve as good tests of potential energy surfaces involving interaction with the O_2 molecule, as clearly indicated by the failure of a square well approximation to provide values of the correct order of magnitude.

The experimental results of the field dependence, obtained empirically without making any assumptions as to the form—only with the assumption that $(1/T_1^{\text{DD}})_0$ is field-independent—show that $f(T)$ is closely approximated by the form

$$f(T) \approx \frac{1}{24} \left(\frac{d_{\text{eff}}}{\langle v \rangle} \right)^{1/2} \left[3 + 7 \left(\frac{\gamma_S}{\gamma_I} \right)^{1/2} \right] \quad (35)$$

This was arrived at by replacing the translational correlation time ($\tau_{\text{trans}} = d^2/D$ in liquid models) by the analogous characteristic time in the gas phase ($d_{\text{eff}}/\langle v \rangle$). It appears that $\pi d_{\text{eff}}^2 \approx \pi d^2 \cdot F(V/k_B T)$ gives a reasonable fit to the experimental field dependence. At 300 K, the values of $f(T)$ ranged from 0.0157 to 0.0243 $\text{MHz}^{-1/2}$ whereas the above expression leads to values of 0.0155–0.0240 $\text{MHz}^{-1/2}$ for CH_4 , CF_4 , SiF_4 , and SF_6 .

1 INTRODUCTION

Surfactants are molecules with two distinctively different parts, one of which is hydrophilic and one which is hydrophobic. This feature of surfactants determines their properties in aqueous or oleic solutions. At low enough concentrations they form molecularly dispersed solutions. As the concentration is increased, they self-assemble into aggregates at a rather well-defined concentration, which is termed the *critical micellar concentration* (cmc) on account of the fact that the aggregates formed are termed *micelles*. As the concentration of surfactant is further increased, the aggregates crystallize into liquid crystalline phases with long-range order, the structures of which may vary rather substantially. The addition of a third component, giving rise to a water–oil–surfactant (where ‘oil’ is taken to be a generic term for an oleic component) system, results in an amazingly rich phase behavior, involving both liquid crystalline phases and liquid solution phases.

The present contribution will be concerned with the characterization by means of NMR techniques of two particular types of liquid solution of surfactant, the first being micellar solutions and the second being microemulsions. Having said this, we run into a problem of definition. How do we decide whether a particular solution belongs to one of these classes or perhaps to yet another class of solutions? Commonly, microemulsions are defined as thermodynamically stable solutions containing a surfactant (where ‘surfactant’ is a generic term for a single surfactant or mixtures of different amphiphilic molecules), water and oil. We shall adhere to this definition. Consequently, a micellar solution is one containing a surfactant and water (possibly with added salt) or oil, while the addition of oil or water to a micellar solution turns it into a microemulsion. Possible ambiguities of these definitions will be pointed out as we go along. [The name ‘microemulsion’ is somewhat unfortunate as it implies that the structure in the solution is one of discrete droplets of either water in oil (W/O) or oil in water (O/W). This is only partly true, as a rich variety of structures can indeed be found in addition to these two droplet structures. The literature is abundant with contributions which ignore this fact and only treat the two droplet structures.]

Studies of surfactant solution systems have had a central place in physical chemistry ever since the pioneering work of McBain at the beginning of this century,^{1–4} not least due to

the fact that these systems have important roles in a variety of applied processes. Questions asked pertain to the structure of the aggregates formed as well as the properties on a molecular level of the molecules comprising the systems.

It is fair to state that NMR has played a central role as a tool in tackling these questions, and much of our current understanding of surfactant solutions derives from NMR studies where two NMR methods have been especially important. The first of these is NMR relaxation studies, which have evolved to become an indispensable tool in studies of liquid surfactant solutions. The second one is measurements of self-diffusion coefficients by means of pulsed field gradients (PFG), an experiment which yields direct and easily interpretable information regarding many different aspects of surfactant solutions. In fact, our present understanding of the structure in microemulsions is to a large extent derived from PFG work in combination with various scattering approaches.

In the present article we discuss the two NMR approaches and describe applications which we consider to be those where NMR has contributed significantly to our present understanding of liquid solution phases of surfactants.

2 SELF-DIFFUSION STUDIES

Measurements of self-diffusion coefficients by means of PFG techniques have evolved to become one of the most important tools in the characterization of liquid surfactant systems. There are essentially two reasons for this, one of which has to do with the measuring technique itself. Thus the PFG approach offers a convenient method of determining self-diffusion coefficients. The technique is outlined in another article in this Encyclopedia (see *Diffusion Measurements by Magnetic Field Gradient Methods*) and has also been described in a number of review articles.^{5,6} Thus we shall not dwell on the technical aspects here. Suffice is to say that the technique requires no isotopic labeling (thus avoiding possible disturbances due to addition of probes); furthermore, it gives component resolved diffusion coefficients with great precision in a minimum of measuring time.

The second reason for its success rests on the fact that the method monitors transport over macroscopic distances (typically of the order of micrometers), and therefore the determined diffusion coefficients reflect aggregate sizes and obstruction effects, yielding information which is easily interpretable in terms of the microstructure of surfactant solutions. The fact that the information is obtained without the need to invoke complicated models, as is the case in the NMR relaxation approach, is particularly important. In this context it should be stressed that the PFG approach measures the self-diffusion rather than the collective diffusion coefficient.

The foundation for the use of NMR to monitor diffusion was laid in 1950 in the seminal paper by Hahn.⁷ Another milestone occurred in the mid-1960s when Stejskal and Tanner demonstrated,⁸ following a suggestion by Douglass and co-workers,⁹ the use of pulsed gradients. Finally, towards the end of the 1960s the method became component resolved when the FT approach was introduced.¹⁰

In its simplest version, the method consists of two equal and rectangular gradient pulses of magnitude g and length δ , sandwiched on either side of the 180° rf pulse in a simple Hahn

echo experiment. For molecules undergoing free (Gaussian) diffusion characterized by a diffusion coefficient of magnitude D , the echo attenuation due to diffusion is given by^{8,11}

$$I(\Delta, \delta, g) = I_0 \exp \left[-\gamma^2 g^2 \delta^2 \left(\Delta - \frac{\delta}{3} \right) D \right] \quad (1)$$

where Δ represents the distance between the two gradient pulses, γ is the magnetogyric ratio of the monitored spin, and I_0 denotes the echo intensity in the absence of any field gradient. By varying either g , δ , or Δ (while at the same time keeping the distance between the two rf pulses constant), D can be determined by fitting equation (1) to the observed intensities.

In the following we use some illustrative examples to show how the PFG approach can be used to obtain information on surfactant solutions.

2.1 Micellar Solutions

2.1.1 The Micellization Process

The PFG method provides a unique way of investigating the process of micellization. The approach is based on the fact that the observed surfactant self-diffusion rates constitute a population weighted average between micellized and monomeric surfactant. This follows since the surfactant lifetime in the micelle is short on the relevant NMR timescale (which is essentially Δ in equation (1), and thus typically around 100 ms). Thus the observed surfactant diffusion coefficient is given by

$$D_{\text{obs}} = p_{\text{mic}} D_{\text{mic}} + (1 - p_{\text{mic}}) D_{\text{free}} \quad (2)$$

where D_{mic} and D_{free} represent the diffusion coefficients of micellized and free surfactant, respectively, and p_{mic} is the fraction of micellized surfactant. Equation (2) can be rearranged to

$$p_{\text{mic}} = \frac{D_{\text{free}} - D_{\text{obs}}}{D_{\text{free}} - D_{\text{mic}}} \quad (3)$$

Clearly, one can obtain the degree of micellization as a function of total surfactant concentration from the concentration dependence of D_{obs} , provided that D_{free} and D_{mic} are known. D_{free} can be obtained from measurements below cmc, while D_{mic} can be obtained from the diffusion coefficient of a hydrophobic probe which is solubilized into the micelles and for which p_{mic} is unity. A suitable probe is hexamethyl-disilane (HMDS) which, if it is added in small amounts (on average one probe per micelle is a recommended concentration), seems only negligibly to disturb the micelles (although for some systems it should be used with some care¹²). Once D_{free} and D_{mic} are known, p_{mic} is obtained without the need to invoke any model for the micellization process. For ionic surfactants the same approach can also be used to obtain the degree of counterion association with the micelles, provided that the counterions contain nuclei suitable for PFG work, which is the case for surfactants with organic counterions.

The result of the approach outlined above is shown in Figure 1, in which a textbook example of the micellization

Figure 1 Self-diffusion data for the surfactant ion ($\text{C}_{10}\text{H}_{21}\text{ND}_3^+$) ($\diamond$) and counterion ($\text{CHCl}_2\text{COO}^-$) ($\blacklozenge$) of a cationic surfactant with an organic counterion. Also given are the diffusion coefficients of the micelles ($\square$), as measured by solubilizing a small amount of HMDS into the micelles. By applying the two-site model given by equation (3) one can estimate both the fraction of micellized surfactant and the degree of counterion binding to the micelles from the diffusion coefficients. For instance, at 140 mM total concentration of surfactant $p_{\text{mic}} = 0.8$, while the degree of counterion binding (defined as the ratio of the concentration of micelle associated counterions to the concentration of micellized surfactant cations) is 0.8. (Data from Jansson and Stilbs.¹³)

process is presented. Data are obtained for a system with an organic counterion.¹³ It is difficult to conceive of any other method that would give the same richness of detail concerning the micellization process. Data such as those presented in Figure 1 have been instrumental in testing various models for describing the micellization process. For instance, approaches based on the Poisson–Boltzmann equation have been very successful in rationalizing the process of micellization for ionic surfactants.^{14,15}

2.1.2 Micellar Size and Structure

Questions pertaining to micellar size and structure may be tackled in two ways by means of PFG studies. The first concerns the measurement of self-diffusion of water (or other small molecules) in the system. Any aggregate present obstructs the diffusion of the water and, as the degree of obstruction depends on the volume fraction of the particles present as well as their geometry, information concerning the latter may be obtained. The mathematical description of such obstruction effects was worked out by Jönsson et al.,¹⁶ who presented results for spheres, prolates, and oblates of different sizes and solution volume fractions.

The other approach to investigating micellar structure is based on Einstein's law, in which the (micellar) diffusion coefficient is related to the frictional factor f through

$$D = \frac{k_B T}{f} \quad (4)$$

where k_B is the Boltzmann constant, and T is the absolute temperature.

The friction coefficient depends on the geometry and size of the diffusing particle as well as on the solvent viscosity η . Expressions relating f to the dimensions exist for several

Figure 2 Micelle hydrodynamic radii for two concentrations of $C_{12}H_{25}(OCH_2CH_2)_5OH$ [(●) 2.73 wt%, (○) 0.92 wt% surfactant] and $C_{12}H_{25}(OCH_2CH_2)_8OH$ [(■) 3.06 wt%, (□) 1.02 wt%]. (Data from Nilsson et al.^{18,19})

different geometries, the simplest being that for a sphere of hydrodynamic radius R_H , which is:

$$f = 6\pi\eta R_H \quad (5)$$

For cases where the geometry is not known, one often uses equation (5) and computes a hydrodynamic radius, on the assumption that the diffusing species is a sphere. An example of this approach is shown in Figure 2, which gives the hydrodynamic radii for micelles formed by nonionic surfactants of the oligo(ethylene oxide) type as a function of temperature. Questions pertaining to the aggregate growth as a function of temperature and concentration in these systems have been the subject of rather lively discussion over the years.¹⁷ Clearly, data such as those presented in Figure 2 are important in this context.^{18–20}

Although the method outlined above is certainly useful, one should be aware of the limitations inherent in the approach. First, equations (4) and (5) assume infinite dilution. As micelles are self-assembled units, one must be aware of the fact that dilution may change their properties. At higher concentrations particle–particle obstruction effects become important, and these must be taken into account.^{21,22}

2.2 Microemulsions

Microemulsions are defined as thermodynamically stable systems containing an oleic solvent (in most basic research a simple hydrocarbon is used), a hydrophilic solvent (most often water or brine), and a surfactant (which can be a combination of several amphiphilic molecules). For weakly amphiphilic molecules the system is molecularly dispersed; this will not be discussed here.

Of particular interest are systems in which small amounts of surfactant may bring equal volumes of oil and water into solution. This can be achieved with less than 1% surfactant, and such systems are usually termed ‘balanced’.²³ In many of these systems one may vary the oil to water volume ratio extensively without ever leaving the one-phase microemulsion

Figure 3 Phase diagram of an alkylpolyglucoside/cosurfactant/water/cyclohexane system at 25 °C with a total surfactant + cosurfactant concentration of 4 wt%. The number of phases present in the various regions of the phase diagram is indicated (for example, the one-phase microemulsion is denoted by 1Φ). (Reproduced with permission from Fukuda et al.²⁴)

region. This is achieved by varying some parameter. Such a parameter is constituted by the temperature in the case of nonionic surfactants of the C_xE_y type, the salinity of the water for ionic surfactants, and the cosurfactant/surfactant ratio in a mixed surfactant system. An example of such behavior is shown in Figure 3, where a recently compiled phase diagram for an alkylpolyglucoside surfactant is displayed. In this case it is the proportion of the cosurfactant (which is a branched alkyl glycerol monoether) in the surfactant mixture which was varied.²⁴

It is a considerable challenge to model such a system, and a prerequisite for such an endeavor is the availability of structural information. It is perhaps in this context that the PFG approach has achieved its most spectacular successes, not least due to the fact that very few other methods can yield such information for microemulsions. How then do we infer structural information from self-diffusion coefficients which are dynamic quantities? The basis of the approach is the fact that the mean distance traveled by the molecules is of the order of $\sqrt{\Delta D}$, which quantity is of the order of micrometers for low molecular weight liquids. Thus any obstruction effects or confinement to droplets of colloidal dimensions affects the diffusion coefficient.

Broadly speaking, one can differentiate between a microstructure of closed particles, whether they are normal (enclosing the oil component) or reversed (enclosing the water), and a microstructure which is bicontinuous. The latter term is often used without being properly defined. We shall take it to imply that a large fraction of both the oil and water molecules exists in domains which span macroscopic distances in three dimensions.

For the case of discrete particles, the continuous phase displays a diffusion behavior similar to that of the neat liquid. There will be solvation effects, i.e. some of the continuous solvent may be associated with the surfactant and, as a consequence, will have an altered diffusional behavior. However, for low surfactant concentration this effect is negligible. Thus any reduction in the reduced diffusion coefficient for the continuous solvent (in PFG studies of microemulsions one preferably reports the reduced diffusion

coefficient, defined as D/D_0 , where D_0 is the bulk diffusion coefficient of the neat liquid at the same temperature) can be attributed to particle obstruction effects (see above). If both the dispersed phase and the surfactant have negligible solubility in the continuous phase, their diffusion is given by the particle diffusion, and so both have the same diffusion coefficient, the value of which can be used to estimate the size of the diffusion particle from equation (4), while the concentration dependence of the diffusion coefficient can be used to infer information about the interaggregate interactions.²²

Turning to the bicontinuous case we note first that both the water and the oil component diffuse rapidly. Careful PFG work using mixtures of oil has revealed that the diffusion process of the oil component is very similar to the diffusion in neat oil.^{25,26} The same holds for the water component.²⁷ This is an important observation, which implies that any reduction in the reduced diffusion coefficient can be attributed to the obstruction effects due to the presence of the surfactant film. Effects such as exchange between droplets and fusion–fission processes cannot explain the rapid oil and water diffusion. Any structural model of microemulsions must not be at variance with this statement. It should be emphasized that, at present, the PFG method is the only way in which bicontinuity may be proved or disproved. Two-dimensional images cannot prove bicontinuity, since it cannot exist in two dimensions.²⁸

Let us now investigate whether the diffusion data for the system in Figure 3 is in line with this reasoning. Figure 4 shows the reduced diffusion coefficients for the water and oil components in the system shown in Figure 3 as a function of the volume fraction of hydrocarbon in the solvent mixture (Φ_{oil}). The data in Figure 4 are typical for microemulsions where the oil content can be varied continuously from no oil to pure oil. Thus the water and oil component diffusion changes continuously from rapid to slow as the fraction of each component is decreased, and the plots of the reduced diffusion coefficients versus the volume fraction of oil in the solvent mixture show a rather characteristic ‘sigmoidal’ curve for both components. At equal volume fractions of oil and water the curves intersect, and the value of both reduced diffusion

Figure 4 The relative self-diffusion coefficients of water ($\diamond$) and hydrocarbon ($\bullet$) as a function of the volume fraction, Φ_{oil} of hydrocarbon in the solvent mixture, for microemulsions formed in the alkylpolyglucoside/cosurfactant/water/cyclohexane system, the phase diagram of which is shown in Figure 3. (Data from Fukuda et al.²⁴)

coefficients is around 0.6 at the point of intersection. In line with the discussion above, this points to discrete particles at low and high values of Φ_{oil} and a bicontinuous structure in between. Based on the information inherent in PFG data such as those presented in Figure 4, how should we picture the bicontinuous microemulsions?

A most fruitful way of looking at these phases is due to Scriven²⁹ who proposed the idea that the structure could be described as a melted liquid crystalline cubic phase, for which the structure is known on account of the scattering studies that can be performed on these systems [cubic phases come in two varieties (discrete and bicontinuous); Scriven had the latter class in mind]. These are formed by two interwoven subvolumes of the same material (polar or nonpolar), which are separated by a film of the opposite material. This dividing film is described as a ‘minimal surface’, having zero mean curvature.

Now, allow this structure to melt, so that the long range order is lost, but locally the structure is retained. When the material on both sides is equal, L_3 phases or bicontinuous micellar solutions (see below) are formed, and the dividing film is a bilayer, while for the case where the two subvolumes are not equal, microemulsions are formed. For this case the dividing film is a monolayer, with a curvature towards the oil or water depending on the volume fraction of the two components.

In an important contribution, Anderson and Wennerström³⁰ have computed the obstruction effect for components in the subvolumes and for components diffusing along the dividing surface. Indeed, these workers found that the reduced diffusion coefficient for a bicontinuous microemulsion with roughly equal oil and water volume fractions is around 0.6, giving further credence to Scriven’s suggestion.

Finally, we note that, when measurements are possible, the value of the surfactant self-diffusion coefficient often displays a maximum with respect to changes in the solvent composition at equal oil and water volume fractions. This observation is more difficult to interpret in terms of a particular microstructure, owing to the difficulties of finding a suitable reference value for the lateral diffusion coefficient for the surfactant along the surfactant film, but it does indicate that the surfactant is diffusing over surfaces that extend over several micrometers with only minor disturbances for diffusions. Consider, for example, the case of a sodium dodecyl sulfate (SDS) microemulsion,³¹ where D for the surfactant was found to be $1.5 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at 27°C , a value which is in good agreement with the values found for lateral diffusion of SDS over a micellar surface of spherical³² ($D = 1.0 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at 30°C) and cylindrical³³ ($D = 1.69 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at 30°C) geometry, where the diffusion is indeed unhindered.

2.3 L_3 -Phases and Bicontinuous Micellar Solutions

The properties of L_3 phases and bicontinuous micellar solutions have been discussed extensively, and they constitute an illustrative example of the power of the PFG method in unravelling solution structure. Both types of solution have a connected structure, and again a fruitful starting point is the (known) structure of the cubic phases. If a cubic phase is diluted with the material of the subvolumes, an L_3 phase

Figure 5 Variation in the reduced water diffusion coefficient with the volume fraction of surfactant in the L_3 ($\diamond$) and cubic ($\blacklozenge$) phases formed in the AOT/water/NaCl system. (Data from Balinov et al.³⁴)

(sometimes known as L^* or ‘sponge’ phase) is formed, while dilution with the material of the dividing film gives rise to a bicontinuous micellar solution. Let us consider the L_3 phase formed in the sodium bis(2-ethylhexyl)sulfosuccinate (AOT)/brine system. In this system, the L_3 phase is in equilibrium with a bicontinuous cubic phase via a two-phase region.³⁴ Figure 5 gives the reduced diffusion coefficients for the water as a function of the surfactant volume fraction Φ_s in both the L_3 and the cubic phase.

There are two noteworthy features of the data shown in Figure 5. First, there is a continuous change in D/D_0 with Φ_s over the two-phase area between the L_3 and cubic phases. Secondly, at high dilution, a limiting value of D/D_0 of around 0.65 is obtained. The first observation indicates that the microstructures in the two phases are similar, since the translational diffusion of water reflects the microstructure of the solution. The second point can be used to infer information about the microstructure in a slightly more rigorous way. Consider a structure of discrete particles. According to the obstruction factors derived by Jönsson et al.,¹⁶ the only geometry that would give rise to a reduction in D/D_0 from 1 to 0.65 would be large disks with an axial ratio in excess of 100:1. This is not in agreement with the surfactant diffusion, which, for the case of disks, implies an axial ratio of 12:1. Thus we are forced to think of alternative microstructures. Following the suggestion inherent in the first feature of the data in Figure 5, i.e. that the microstructures are similar in the L_3 and cubic phases, let us consider the case of a bilayer continuous structure. As noted above, this case has been treated by Anderson and Wennerström,³⁰ who obtained a value of 0.65 for the reduced diffusion coefficient for the solvent diffusion at low volume fraction of bilayer (in fact, for an infinitely thin multiply connected bilayer, the limiting value is $\frac{2}{3}$, on account of the dimensionality of the bilayer). Moreover, by analyzing the dependence of D/D_0 on Φ_s , information can be obtained regarding the coordination number of the obstructing surface.³⁵

The analysis of the bicontinuous micellar solution structure as based on PFG data follows the same approach as the one described above. Readers interested in this particular micellar solution are referred to the paper by Monduzzi et al.³⁶

Figure 6 A ^1H NMR FT PFG experiment at 100MHz on the solubilization of neopentanol into dodecyltrimethylammonium chloride micelles (solvent D_2O). The degree of solubilization is obtained directly from the evaluated D values for neopentanol in the micellar solution and in an aqueous solution [see equation (3)]. The value for the micellar diffusion coefficient, which is obtained from a small amount of solubilized tetramethylsilane (TMS), is also needed. The gradient current was varied linearly between successive spectra, which were obtained at fixed intergradient (Δ) and rf pulse (τ) intervals

2.4 Solubilization

As a final illustration of the power of the PFG approach, we consider the topic of solubilization. By ‘solubilization’ we mean the incorporation of molecules which are not water soluble into the micellar subvolume of a micellar solution. An important question pertaining to the phenomenon of solubilization concerns the degree of partitioning between the micelles and the water. This question is related to that pertaining to the micellization process (see above), and the same approach used to study that process can be used to investigate solubilization. Thus the degree of solubilization p can be determined by measuring the diffusion coefficient of the solubilize in the absence and presence of micelles, and determining the diffusion coefficient for the micelle (using the approach outlined above) by using equation (3). From the volume or weight fraction of the micellar subvolume and the value of p , one can then determine the desired partition coefficient. A typical PFG solubilization experiment is shown in Figure 6.³⁷

There are several advantages of the PFG approach as compared with other techniques for studying solubilization. The experiment is simple as well as selective. The latter point is particularly important, as one can determine the solubilization of several different solubilizes simultaneously, and each individual value of p can be determined. The presence of impurities is normally not a problem. The quantity p is well defined and easily interpreted. Finally, by measuring the surfactant diffusion one can independently check whether the micelles as such are altered by the presence of solubilizes. Clearly, the whole topic of solubilization becomes somewhat less meaningful if one does not have control over the state of the micelles.

3 RELAXATION STUDIES

NMR relaxation has proven to be a useful experimental technique for studying surfactant aggregation in liquid solutions

and liquid crystals.^{20,38–40} The experiment yields information on the local dynamics and conformational state of the surfactant hydrocarbon chain and has demonstrated the liquid-like interior of surfactant micelles. However, the main purpose of NMR relaxation studies of isotropic micellar solutions and microemulsions has been to study properties such as the aggregate size.

The reorientation dynamics of aggregated surfactant molecules, which are discussed in more detail below, are characterized by the fact that they locally have a preferred orientation, forming essentially a monomolecular film of oriented molecules. Locally, surfactant molecules undergo rapid internal motions, such as *trans*–*gauche* isomerizations in the hydrocarbon chain. These motions are, due to the preferred orientation, slightly anisotropic. The situation can be pictured as the polar headgroups being anchored at the polar–apolar interface, leaving room for dangling motions of the hydrocarbon chains, with certain restrictions on the number of conformations due to packing constraints in the film. In isotropic solutions the residual interaction or anisotropy is further averaged by the thermal tumbling of the aggregates in combination with the diffusion of surfactant molecules within the curved surfactant film.

NMR spectra from surfactants in micellar solutions and microemulsions are generally in the motional narrowing regime, and the spin dynamics are characterized by well-defined relaxation times. Exceptions can be found in solutions of very long ($>10^2$ nm) wormlike cylindrical micelles where the large size in connection with steric overlap gives rise to a very slow (about 10^{-4} s) aggregate reorientation.^{41,42} On the other hand, the dynamics are typically outside the extreme narrowing regime, and one often observes $R_2 \gg R_1$, where R_1 and R_2 are the longitudinal and transverse relaxation rates, respectively. Micellar aggregates reorient on a timescale of 10^{-9} s or slower. Thus, at conventional magnetic field strengths, the essential information on the surfactant aggregates is stored in the transverse relaxation rate R_2 .

A hydrocarbon, typically an alkyl chain of 12–16 carbon atoms, constitutes the major part of surfactant molecules, offering ^1H and ^{13}C nuclei for NMR studies. Being spin- $\frac{1}{2}$ nuclei, the relaxation is mainly due to dipole–dipole interactions (although chemical shift anisotropy and scalar interaction can sometimes be important in the case of ^{13}C). The easy access and the relatively high sensitivity (which was particularly important in early CW NMR studies) has made ^1H NMR (in particular bandwidth measurements) studies particularly popular. Micellar growth can easily be studied qualitatively by monitoring the bandwidth of aliphatic ($-\text{CH}_2-$) protons in the spectrum. Quantitative analysis is, however, complicated by the coupling of the various protons having locally different motional characteristics along the alkyl chain. In an alkyl chain of, say, 16 carbon atoms, the protons constitute a coupled spin system of approximately 2^{16} spin states, which can have a broad spectrum of transition rates, resulting in significant deviations from a Lorentzian bandshape of the CH_2 resonance.^{41,43} This complexity can, however, be turned into an advantage in that it allows for a continuum description of the transition rate spectrum. The ^1H bandshape problem was analyzed by Wennerström et al.^{41,43} within the two-step formalism (see below), and quantitative ^1H bandshape analyses have been performed in systems of

large, slowly reorienting micelles.^{41,42} In contrast to the non-Lorentzian band shape, one often observes an exponential longitudinal relaxation due to rapid internal equilibration of the spin system (spin diffusion), and the frequency dependence of R_1 has been measured by using field cycling techniques.^{44,45}

In an alkyl chain, the ^{13}C nuclei are relaxed by the fluctuating dipole–dipole coupling to the directly bound protons. The various carbon atoms along the chain are normally resolved. Usually, one applies broadband proton decoupling, resulting in exponential longitudinal relaxation of the individual ^{13}C magnetizations, and it is possible to determine R_1 and the nuclear Overhauser enhancement of the different methylene segments. On the other hand, it is difficult to measure R_2 on ^{13}C . Therefore, ^{13}C is mainly useful for studying local chain dynamics and segmental order, since the aggregate dynamics occur on timescales which are normally long relative to the inverse ^{13}C resonance frequency.

Certain surfactants carry phosphate or ammonium polar headgroups, offering ^{31}P and ^{14}N nuclei, respectively, for relaxation studies. The phosphate ^{31}P ($I = \frac{1}{2}$) has a relatively large chemical shift anisotropy which is strongly dependent on the pH (degree of protonation), complicating the analysis of relaxation data. ^{14}N is a $I = 1$ nucleus and its relaxation is dominated by the strong quadrupolar interaction. Except for the case of quaternary ammonium groups, the magnitude and asymmetry of the quadrupolar coupling is also pH dependent, and special care has to be taken.

The most suitable nucleus for relaxation studies of surfactant systems is ^2H , which can be incorporated synthetically into the hydrocarbon chain of the surfactant molecule. Normally, one selectively labels a single methylene segment, typically one adjacent to the polar headgroup, in order to avoid resonance overlap in the spectrum. ^2H is a $I = 1$ nucleus, and the dominating interaction governing the relaxation is the strong quadrupolar interaction. For aliphatic ($\text{C}-^2\text{H}$) deuterons, the analysis is further simplified by the fact that the electric field gradient tensor has essentially cylindrical symmetry around the $\text{C}-^2\text{H}$ bond direction, resulting in a vanishing asymmetry parameter. The ease with which both R_1 and R_2 can be accurately measured, the relatively simple interaction Hamiltonian, and the sufficiently high sensitivity allowing measurements to be made at low resonance frequencies (down to 2 MHz using variable field electromagnets), give ^2H NMR relaxation a particularly important role among the different experimental tools available for studying surfactant systems.

The utility of the NMR technique as an experimental tool in surfactant science can be made apparent by comparing the strengths and weaknesses of the NMR relaxation technique with those of other experimental techniques. In comparison with other experimental methods used in studying, for example, micellar size, the NMR relaxation technique has two major advantages, both of which are associated with the fact that it is reorientational motions which are measured. One is that the relaxation, i.e. R_2 , is sensitive to small variations in micellar size. Consider, for example, a sphere for which the rotational correlation time is proportional to the cube of the radius. This can be compared with the translational self-diffusion coefficient which varies linearly with the radius. The second, and perhaps most important advantage is the fact that the rotational diffusion of particles in solution is essentially independent of interparticle interactions (electrostatic and hydrodynamic). This is in contrast to most

other techniques (such as viscosity, collective and self-diffusion, scattered light intensity, etc.) available for studying surfactant systems or colloidal systems in general. In this latter respect, NMR relaxation experiments are comparable with form factor determinations with small angle X-ray or neutron scattering experiments. A weakness of the NMR relaxation approach to aggregate size determinations, compared with form factor determinations, would be the difficulties of absolute calibration, since the transformation from information on dynamics to information on structure must be performed by means of a motional model.

3.1 Timescale Separation: The Two-Step Model

In this section we discuss a motional model^{46–48} of aggregated surfactant molecules, which involves a timescale separation of fast local and slow global motions. This model has been applied extensively to, and shown to rationalize, NMR relaxation data from aggregated surfactant systems. We discuss the model in connection with ^2H relaxation experiments, since the most extensive experimental studies have been performed on ^2H -labeled surfactants. We begin by recalling that the longitudinal (R_1) and transverse (R_2) relaxation rates of an $I = 1$ nucleus, due to the quadrupolar interaction in an isotropic solution, are given by⁴⁹

$$R_1 = \frac{3\pi^2}{40} \chi^2 [2j(\omega_0) + 8j(2\omega_0)] \quad (6a)$$

$$R_2 = \frac{3\pi^2}{40} \chi^2 [3j(0) + 5j(\omega_0) + 2j(2\omega_0)] \quad (6b)$$

where χ is the quadrupolar coupling constant, and $j(\omega_0)$ is the reduced spectral density function evaluated at the Larmor frequency ω_0 .

Based on existing knowledge of surfactant aggregate structures, Wennerström and co-workers^{46–48} suggested that the reorientational motion of surfactant molecules can be divided into: (i) fast local motions (equilibration of internal modes), which are slightly anisotropic due to the preferred orientation of the surfactant molecules; and (ii) slow isotropic motions, associated with the aggregate tumbling and the lateral diffusion of surfactant molecules within the aggregates. If these two motions occur on significantly different timescales, the fast motions generate a well-defined residual anisotropy to be averaged by the slow motions, and the spectral density can be written as a weighted sum of the fast and the slow components

$$j(\omega_0) = (1 - S^2)j_f(\omega_0) + S^2j_s(\omega_0) \quad (7)$$

where $j_f(\omega_0)$ and $j_s(\omega_0)$ are the reduced spectral density functions describing the fast and slow motions, respectively. The parameter S is often referred to as an ‘order parameter’ and is given by the average

$$S = \frac{1}{2} \langle 3 \cos \theta_{\text{MD}} - 1 \rangle_f \quad (8)$$

where θ_{MD} is the angle between the axis of the maximum component of the electric field gradient tensor and the director axis.

The situation for the case of a ^2H -labeled methylene segment of a surfactant molecule residing in a micelle is

Figure 7 Schematic illustration of the various coordinate frames considered within the two-step model, for the case of a specifically ^2H -labeled methylene segment in the surfactant hydrocarbon chain. The laboratory frame (L) is set by the direction of the external magnetic field, where Z_L is the field direction. In this frame the nuclear quadrupolar moment tensor is diagonal. The director frame (D) is associated with the micellar aggregate, where Z_D specifies the micellar surface normal. It is assumed that the fast local dynamics occur with an essentially cylindrical symmetry around Z_D . The molecular frame (M) corresponds to the principal axis of the electric field gradient tensor. For the case of a methylene segment, Z_M specifies the maximum component of the field gradient tensor, which is also cylindrically symmetric around Z_M

illustrated in Figure 7. The director axis Z_D corresponds to the micellar surface normal. The field gradient tensor is cylindrically symmetric around the C–D bond axis, with the maximum component in the bond axis direction Z_M .

In equation (7) it is also assumed that the fast motions have an effective three-fold or higher symmetry around the director. For most situations, however, one may expect an effectively cylindrical symmetry. For lower than three-fold symmetry, equation (7) must be extended to include a second-order parameter, describing the residual order in the plane perpendicular to the director. A similar extension is also necessary when the electric field gradient has a nonvanishing asymmetry parameter (for an extensive discussion, see Halle and Wennerström⁴⁸).

3.2 Frequency Dependent Relaxation Studies of Small Spherical Micelles

The fast motions, described by the spectral density function $j_f(\omega_0)$, are expected to occur on a similar timescale ($\tau_f \approx 10^{-11}$ s) as in the corresponding liquid alkane. Thus this motion is in extreme narrowing ($\tau_f \ll 1/\omega_0$) in the accessible frequency range, and we may assume that $j_f(2\omega_0) \approx j_f(\omega_0) \approx j_f(0) = 2\tau_f$, where τ_f should be considered as an effective correlation time, representing the integral over a nonexponential correlation function.

The slow motion is a combination of micelle tumbling and the lateral diffusion of surfactant molecules within the surfactant film. For spherical aggregates, this motion is described by a Lorentzian spectral density function:

$$j_s(\omega_0) = \frac{2\tau_s}{1 + (\omega_0\tau_s)^2} \quad (9)$$

where τ_s is the correlation time. The tumbling and the lateral diffusion are expected to be statistically independent, in which case the correlation function can be factorized:

$$G_s = G_t G_d = e^{-t/\tau_t} e^{-t/\tau_d} = e^{-t/\tau_s} \quad (10)$$

where subscripts t and d refer to tumbling and lateral diffusion, respectively, and the slow correlation time can be written as

$$\frac{1}{\tau_s} = \frac{1}{\tau_t} + \frac{1}{\tau_d} \quad (11)$$

The correlation time associated with the tumbling of a sphere of radius R is given by

$$\tau_t = \frac{4\pi\eta R^3}{3k_B T} \quad (12)$$

where η represents the solvent viscosity, and $k_B T$ is the thermal energy. The effect of lateral diffusion can be described in terms of diffusion on the surface of a sphere of radius R . In this case, the correlation time can be written as

$$\tau_d = \frac{R^2}{6D_{\text{lat}}} \quad (13)$$

where D_{lat} is the lateral diffusion coefficient.

With the assumptions of (i) extreme narrowing conditions for the fast motions and (ii) a Lorentzian spectral density function of the slow motion, the expressions for the relaxation rates become, with equation (7)

$$R_1 = \frac{3\pi^2}{40} \chi^2 \left\{ (1 - S^2)20\tau_f + S^2 \times \left[\frac{4\tau_s}{1 + (\omega_0\tau_s)^2} + \frac{16\tau_s}{1 + (2\omega_0\tau_s)^2} \right] \right\} \quad (14a)$$

$$R_2 = \frac{3\pi^2}{40} \chi^2 \left\{ (1 - S^2)20\tau_f + S^2 \times \left[6\tau_s + \frac{10\tau_s}{1 + (\omega_0\tau_s)^2} + \frac{4\tau_s}{1 + (2\omega_0\tau_s)^2} \right] \right\} \quad (14b)$$

Equations (14a) and (14b) have been applied in a large number of ^2H NMR relaxation studies of micellar systems. It turns out that frequency dependent relaxation studies are particularly useful for studying small spherical micelles, which typically have a radius of about 2 nm. Using the water viscosity and equation (12) we obtain $\tau_t \approx 7$ ns at room temperature (25 °C). Including the effect of lateral diffusion, a typical value of the slow correlation time is $\tau_s \approx 5$ ns. Thus, the relaxation dispersion from the slow motion occurs around ν_0

Figure 8 The variation in R_1 and R_2 with the Larmor frequency for ^2H nuclei bound to the α -methylene segment of the surfactant hexadecyltrimethylammonium chloride. The sample was an aqueous micellar solution containing 13 wt% of the surfactant. Experiments were performed at 27 °C. (Data from Söderman et al.⁵¹)

$\approx (2\pi\tau_s)^{-1} \approx 30$ MHz, which is well within the accessible Larmor frequency range for ^2H .

To investigate the applicability of the motional model, Söderman and co-workers^{50,51} studied aqueous micellar systems of alkyltrimethylammonium chloride surfactants of two different alkyl chain lengths: dodecyl and hexadecyl chains. The alkyl chains were ^2H labeled in the α -methylene segment, adjacent to the ammonium polar headgroup, and the relaxation rates R_1 and R_2 were measured in the Larmor frequency range 2–55 MHz, in order to cover the dispersion of the slow motion. The lower frequencies were obtained by using a variable field electromagnet. The results⁵¹ obtained for the hexadecyltrimethylammonium chloride micelles (concentration 13 wt%) are shown in Figure 8. The solid lines are best fits of equations (14a) and (14b) to the whole data set, using τ_f , τ_s , and S as adjustable parameters. As can be seen from Figure 8, the data are well described by a Lorentzian spectral density function superimposed on a constant offset in the investigated frequency range, thus supporting the assumption of timescale separation. The fit yielded $\tau_f = 42 \pm 1$ ps, $\tau_s = 7.6 \pm 0.4$ ns, and $S = 0.186 \pm 0.003$, where the uncertainties correspond to an approximately 80% confidence interval taking only random errors into account, and a value of $\chi = 167$ kHz was used for the quadrupolar coupling constant.

The slow correlation time was interpreted in terms of equations (11)–(13), which contain two unknown parameters, R and D_{lat} . However, D_{lat} can be measured in phases of extended surfactant films, such as bicontinuous cubic phases, and R is expected to be close to the overall length of the surfactant molecule. Using $D_{\text{lat}} \approx 1 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$, as measured in a bicontinuous cubic phase of the similar surfactant hexadecylammonium fluoride, and the radius $R = 2.37$ nm, a slow correlation time of approximately 10 ns was calculated from equations (11)–(13), which is in reasonable agreement with the experimentally determined value.

The applicability of the two-step model receives further support when comparing the S value obtained from the fit to the relaxation dispersion with that measured from quadrupolar

splittings in liquid crystalline phases formed at higher surfactant concentrations. In the liquid crystalline phases, extended surfactant aggregates are 'locked' in a crystalline array. Two very common structures are the lamellar phase, where surfactant bilayers are stacked with one-dimensional order, and the hexagonal phase, where cylindrical aggregates are packed on a two-dimensional hexagonal lattice. In these phases one has effectively frozen the slow motion, and the nuclei experience a static quadrupolar Hamiltonian $\langle \hat{H}_Q \rangle_f$ in addition to the Zeeman term, where the average is taken over the fast local motions. This results in a quadrupolar splitting of magnitude⁴⁶

$$\Delta_{\text{lam}} = \frac{3}{4} \chi |S| \quad (15)$$

in the lamellar phase with planar films. In the hexagonal phase, the rapid surfactant diffusion around the cylinder axis results in an additional averaging of the interaction by a factor of 2 and the splitting is given by

$$\Delta_{\text{hex}} = \frac{3}{8} \chi |S| \quad (16)$$

One may expect that the local motions, and hence the S value, should be similar in the liquid crystalline surfactant aggregates and the micelles in the dilute solution phase. This is in fact found to be the case. As mentioned above, the S value obtained from the fit to the relaxation dispersion (Figure 8) was found to be $S = 0.186$. A very similar value (0.192) was measured in the hexagonal phase at higher concentrations.⁵¹

3.3 Larger Aggregates: Use of the Zero Frequency Spectral Density

The small spherical micelles ($R \approx 2$ nm) can be seen as a limiting case, and in general surfactant aggregates have much larger extensions. When the size of the aggregates increases, τ_s increases as well, and the relevant relaxation dispersion moves out of the accessible frequency window. In some extreme cases, for example with long, entangled wormlike micelles, the dynamics may even move out of motional narrowing, showing slow motion effects in the NMR spectrum.⁴² However, for most micellar and microemulsion systems, the motional narrowing condition applies. In these cases, valuable information may be obtained by measuring R_1 and R_2 for ^2H -labeled surfactants at a single Larmor frequency. For larger aggregates, the relevant information on the aggregate size is contained in the zero frequency spectral density only. Assuming that the fast motions are in extreme narrowing, in which case they contribute to a constant offset of both R_1 and R_2 , it is useful to consider the difference $\Delta R = R_2 - R_1$ which then depends only on the slow motions. For the case of very slow motions, we also have $j_s(0) \gg j_s(\omega_0) \approx j_s(2\omega_0)$, and ΔR can be approximated by

$$\Delta R = \frac{9\pi^2}{40} (\chi S)^2 j_s(0) \quad (17)$$

This expression has been used to study variations in the shape of surfactant aggregates in different microemulsion

systems.^{52,53} Here, the micellar aggregates are swollen by the addition of a third component (normal micelles in aqueous solution are swollen by oil; reverse micelles in oil are swollen by water), where spherical aggregates can have radii of the order of 10 nm. Quantitative applications of equation (17) require reliable determinations of S from adjacent liquid crystalline phases. Furthermore, they require assumptions concerning the aggregate shape, and a knowledge of D_{lat} , to determine, for example, an aggregate radius of spherical aggregates. So, obviously, there are some uncertainties involved concerning the 'absolute calibration' of the method.

The situation can, however, be optimized by noting that the aggregates are formed under the constraint of a constant average interfacial area/enclosed volume ratio, set by the surfactant/internal component concentration ratio. With this constraint, the minimum aggregate size corresponds to a spherical shape. Due to the entropy of mixing, spherical aggregates, representing the minimum aggregate size, will always be stable at high dilutions, where the experiment can be calibrated. In many cases, D_{lat} is also known quite accurately from the various bicontinuous phases of the different systems.

Deviations from spherical shape can be modeled as a growth into prolate or oblate shapes. The interfacial area/enclosed volume constraint implies a constraint on the possible values of the two semiaxes describing the particle size. Halle⁵⁴ has calculated the correlation functions for the combined particle tumbling and surface diffusion of prolate and oblate particles. His results have been applied to, for example, microemulsion systems,^{52,53} focusing on the ratio $j_{s,\text{pr}}(0)/j_{s,\text{sph}}(0)$, where the subscripts pr and sph refer to prolate and spherical particles, respectively. For a given interfacial area/enclosed volume ratio, which specifies the radius R of the sphere, $j_{s,\text{pr}}(0)/j_{s,\text{sph}}(0)$ is a function of the prolate axial ratio D_{lat} , and R . Knowing D_{lat} and R from other experiments it is possible to determine the aggregate axial ratio from the relaxation experiment.

As mentioned above, the strength of the NMR relaxation technique in comparison to other (e.g. scattering) techniques for studying micelles and microemulsions is related to the fact that rotational dynamics are monitored. This has the advantages that (i) the dynamics are sensitive to small size variations, and (ii) the dynamics are essentially independent of interactions. In an extensive study of a three-component microemulsion system composed of the nonionic surfactant pentaethyleneoxide dodecyl ether, water, and decane, oil swollen micelles dispersed in water were investigated over a large concentration range.⁵²

With a nonionic surfactant, spherical aggregates are formed at lower temperatures, while the aggregates grow in size with increasing temperature.¹⁷ Figure 9 shows the variation of ΔR with temperature for two compositions, $\Phi = 0.12$ and 0.23, in the microemulsion phase.⁵² Here, $\Phi = \Phi_s + \Phi_o$ is the total volume fraction of surfactant (Φ_s) and oil (Φ_o), and the ratio $\Phi_s/\Phi_o = 0.815$ was kept constant.

The value of ΔR decreases when the temperature is decreased in the microemulsion phase and levels off at lower temperatures at a minimum value ΔR_{min} , when the aggregates have reached the limiting spherical shape, corresponding to the minimum size. Note that the minimum ΔR value is the same for the two concentrations, as is expected because the radius, dictated by Φ_s/Φ_o , should be the same. By considering

Figure 9 Variation in ${}^2\text{H}$ $\Delta R = R_2 - R_1$ with temperature of the ${}^2\text{H}$ -labeled nonionic surfactant pentaethyleneoxide dodecyl ether $[\text{CH}_3(\text{CH}_2)_{10}\text{C}^2\text{H}_2(\text{OCH}_2\text{CH}_2)_5\text{OH}]$ in a ternary system with water and decane. The ratio Φ_s/Φ_o is 0.815, where Φ_s and Φ_o are the surfactant and oil volume fractions, respectively. The concentrations are $\Phi = \Phi_s + \Phi_o = 0.12$ and 0.23 , respectively. (Data from Leaver et al.⁵²)

the reduced ΔR value, $\Delta R/\Delta R_{\min} = j_{s,\text{pr}}(0)/j_{s,\text{sph}}(0)$, it was possible to calculate the increase in the axial ratio of the aggregates with increasing temperature, assuming a growth into prolate aggregates. The variation in the axial ratio obtained is shown in Figure 10.

Very large micelles may also form in binary surfactant systems. These are long wormlike micelles which become entangled at higher concentrations, giving rise to rheological properties similar to those in polymer solutions. Such systems have been examined by means of ${}^1\text{H}$ bandshape analysis.^{41,42} The protons of the surfactant hydrocarbon chain form a very large dipolar coupled spin system, with essentially a continuum distribution of transverse relaxation rates. The distribution of relaxation rates is related to the distribution of order parameters,⁴³ which can be obtained from analyzing the bandshape in the liquid crystalline (lamellar or hexagonal)

Figure 10 Variation in the micellar axial ratio with temperature, assuming a monodisperse prolate growth, as deduced from the relaxation data in Figure 9 by using the correlation function due to Halle,⁵⁴ for the combined motion of aggregate tumbling and surface diffusion

phases, where the bandshape is associated with a continuum distribution of residual dipolar splittings.⁵⁵

Slow motions have also been studied by measuring the differential line broadening (DLB) of proton J coupled ${}^{13}\text{C}$ nuclei.⁵⁶ Here the difference in bandwidth of the different resonances in a ${}^{13}\text{C}$ multiplet can be attributed to the interplay between the dipole–dipole and chemical shift anisotropy relaxation mechanisms, and by analyzing the difference, information on the slow motion may be obtained.

3.4 Relaxation Measurements on Water and Counterion Nuclei

Relaxation measurements on water and counterion nuclei may also give information about the surfactant aggregate size and shape. Such measurements may be particularly useful in reverse micellar systems, where water and surfactant counterions are contained in small water pools covered by a surfactant monolayer. In a ${}^{23}\text{Na}$ ($I = \frac{3}{2}$) spin relaxation study of a reverse micellar system, the presence of slow motions was found to result in a biexponential free induction decay (FID).⁵⁷ Using the two transverse relaxation rates and an effective longitudinal relaxation rate, it was possible to determine all three spectral density values: $j(0)$, $j(\omega_0)$, and $j(2\omega_0)$. From the fit of the imaginary part of the FID it was also possible to determine the second-order quadrupolar dynamic shift, allowing for an additional test of the motional model invoked in the interpretation of the data.

An interesting application of water nuclei relaxation in microemulsions concerns the so-called ‘nuclear spin quenching’ studied by Carlström and Halle.⁵⁸ Here, the effect of chemical exchange of water protons, mediated by the presence of prototropic ions, H_3O^+ and OH^- , on the ${}^{17}\text{O}$ bandshape in a reverse micellar system was investigated. By careful analysis of the ${}^{17}\text{O}$ bandshape, information on the water exchange kinetics between droplets as well as the droplet size was obtained.

3.5 Surfactant Hydrocarbon Chain Conformations in Micelles

The early findings of narrow ${}^1\text{H}$ bands from the surfactant hydrocarbon chains in small spherical micelles revealed that the micellar interior is in a liquid-like state. Magnetic field dependent ${}^{13}\text{C}$ R_1 relaxation experiments confirmed those ideas, and a segmental order parameter profile, similar to that obtained from ${}^2\text{H}$ quadrupolar splittings in lipid bilayer systems, was obtained within the two-step formalism.⁵⁹ By studying the dynamics of a symmetric probe molecule solubilized in micelles, it was concluded that the micellar interior was characterized by an effective viscosity similar to that of the neat hydrocarbon.⁶⁰

Chachaty and co-workers^{40,61} have studied the enhanced relaxation rate due to the presence of paramagnetic counterions. The multivalent paramagnetic counterion is expected to be selectively adsorbed onto the charged micellar surface. Thus, by analyzing the effect on the ${}^{13}\text{C}$ relaxation along the chain, the distribution in the distance from the micellar surface could be estimated for the various methylene segments.

A conceptually similar study was reported recently by Palmas et al.⁶² Here, cross relaxation effects between ^{13}C and nondirectly bonded protons were examined by two-dimensional heteronuclear Overhauser effect spectroscopy (HOESY). This study revealed the significance of intermolecular ^1H – ^{13}C dipolar interactions. Correlations between carbon atoms and protons belonging to different segments were observed in the lower part of the hydrocarbon chains, while they were found to be absent in the vicinity of the polar head-group, where the chain configuration is more rigid.

1 INTRODUCTION

The information provided by the frequency dependence ('dispersion') of spin-lattice relaxation times (or rates) in the laboratory frame T_1 (T_1^{-1}), or in the rotating frame $T_{1\rho}$ ($T_{1\rho}^{-1}$), is the type and the timescale of molecular motion. Studies of this sort are mainly based on the field cycling [or NMR dispersion (NMRD)] technique^{1,2} often supplemented by rf pulse experiments in stationary magnetic fields. Molecular dynamics can be specified on this basis in great detail, although chemical shift distributions normally cannot be resolved.

The essence of the field cycling principle is to generate nonequilibrium spin populations by switching the magnetic field to a variable relaxation field, the flux density of which is normally lower than that of the polarization field. The relaxation curve of the magnetization is then probed point by point by switching to a fixed detection field, where the magnetization is read out in the form of a FID or a spin echo. A prerequisite of the technique is that relaxation during the switching intervals is minor. The maximum frequency is determined by technical restrictions, whereas the lower frequency limit is given by the local fields within the sample or by incompletely compensated external fields such as the Earth field. Operational order-of-magnitude ranges of the frequency are $10^3 < \nu < 10^8$ Hz for protons and $10^2 < \nu < 10^7$ Hz for deuterons.

Molecular motions cause fluctuations of the spin interactions; these are normally the dipolar interaction among the spin-bearing particles or the coupling of quadrupole nuclei to electric field gradients. The fluctuating interactions induce spin transitions, making the ensemble relax towards equilibrium. The spin-lattice relaxation rate $1/T_1$ in *homogeneous systems* is given by intensity functions (or spectral densities) $I(\omega)$ at the transition frequencies ω of the spin system.³ These functions are proportional to the FTs of the time autocorrelation functions of spherical harmonics of order 2, $G(t)$. The fluctuations of quadrupolar interactions and the low-frequency part of

fluctuations of dipolar interactions are normally dominated by intramolecular contributions. The T_1 frequency dispersion thus probes the correlation function (or the corresponding intensity function) of molecular reorientations and, in certain circumstances, translations.

Systems of biological origin tend to be *heterogeneous* in the sense that the investigated nuclei occur in different environments with different molecular dynamics and spin interactions. It is then a matter of exchange rates whether spin-lattice relaxation is determined by average intensity functions ('fast exchange' relative to relaxation times) so that monoexponential relaxation decays arise, or whether multiexponential distributions occur.⁴ In the context of water relaxation in biological systems, the two-site fast exchange model turned out to be very successful. Note, however, that the term 'exchange' refers to material transport as well as to (immaterial) spin diffusion or magnetization transfer.^{12,13}

The element usually detected in T_1 frequency dispersion experiments is hydrogen, via proton or deuteron resonance. (In exceptional cases, ^{31}P relaxation studies might also be feasible.⁵) Other nuclear species can be probed indirectly via cross relaxation if their relaxation rates are fast enough to act in combination with proton spin diffusion as relaxation sinks. This can be expected in particular with quadrupole nuclei. The cross relaxation then manifests itself as 'quadrupole dips' at the resonance crossing frequencies,⁶ as demonstrated in Figure 1 for polyaniline protons cross relaxed by the amide ^{14}N relaxation sinks.

The T_1 frequency dispersion may be influenced further by electron paramagnetic constituents such as, for example, molecular oxygen,⁸ paramagnetic ions,^{9,10} or heme groups.^{7,11} Relaxation mechanisms of this sort, however, are not considered in this article.

T_1 frequency dispersion studies have been performed with many different (diamagnetic) systems of biological origin, including: dissolved,^{12,14} wet,¹⁵ or dry¹⁶ proteins; DNA;⁶ lipid bilayers;^{17,18} tissue;¹⁵ eye lenses;¹⁹ and small animals *in vivo*.²⁰

The dominant constituents of biological systems are biopolymers (or oligomers) and water. The water component (including all exchangeable hydrogen atoms of the biopolymers) can be conveniently prepared in deuterated form so that separate studies of the dynamics in the two components can be performed. Figure 2 shows the T_1 frequency dispersions of water deuterons and of nonexchangeable biopolymer protons measured in a solution of bovine serum albumin (BSA) in D_2O as a typical system.²¹ The entirely different nature of the fluctuations within the two constituents is obvious.

2 FLUCTUATIONS IN PROTEINS

Molecular motions of proteins can comprise main chain ('backbone') fluctuations, side-group motions and tumbling of the whole macromolecule. The latter can easily be identified by considering the concentration dependence of the reorientation rates (see below). Side-group motions, such as restricted rotational diffusion and ring flips, are a matter of the local structure and chemical composition. Proteins, for instance, therefore tend to be characterized by a broad distribution of the side-group correlation times.

Figure 1 (a) Field dependence of the ^1H and ^{14}N resonance frequencies of amide groups. The hatched areas indicate the range covered in a powdery sample. The solid lines within these areas represent the powder averages. The magnetic flux density B_0 is expressed in units of the proton Larmor frequency. (b) T_1 frequency dispersion of poly-L-alanine at -1°C . The three ^{14}N - ^1H quadrupole dips at the resonance crossings are obvious. (Reproduced by permission of Academic Press from R. Kimmich, F. Winter, W. Nussler, and K.-H. Spohn, *J. Magn. Reson.*, 1986, **68**, 263)

Backbone fluctuations in proteins and polypeptides, on the other hand, appear to be governed by homogeneous modes leading to an apparently universal T_1 dispersion behavior at low frequencies where side-group motions are of minor importance. The frequency dependence in the absence of molecular tumbling can be described over a wide range by the power law⁶ $T_1 \propto \nu^{0.74 \pm 0.06}$, which can be explained by one-dimensional multiple trapping diffusion of defects locally dilating the structure.¹⁶ The corresponding correlation function is given by the error function ('erf') expression:

$$G_{\text{mtd}}(t) = a_1 \left\{ \text{erf} \left(\frac{b^2}{2\langle \xi^2 \rangle} \right)^{1/2} - \left(\frac{2\langle \xi^2 \rangle}{\pi b^2} \right)^{1/2} \times \left[1 - \exp \left(-\frac{b^2}{2\langle \xi^2 \rangle} \right) \right] \right\} + a_2 \quad (1)$$

Figure 2 Frequency dependence of the proton (●) and deuteron (○) spin-lattice relaxation times of a D_2O solution of bovine serum albumin (35 wt.%) at 291 K. The data in the vicinity of the ^{14}N - ^1H quadrupole dips are omitted. The different T_1 frequency dispersions indicate different fluctuation processes dominant for water (including exchangeable hydrogen atoms) and for the protein molecules. (Reproduced by permission of the American Chemical Society from W. Nussler and R. Kimmich, *J. Phys. Chem.*, 1990, **94**, 5637)

where $a_2 = 1 - a_1$ represents the residual correlation at long times, b represents the extension of the defect, and $\langle \xi^2 \rangle \propto t^{1/2}$ represents the (anomalous) mean-square displacement of the defects in a time interval t .

3 FLUCTUATIONS IN LIPID BILAYERS

Lipid bilayers form another system whose dynamics are governed by dynamic modes. In experiments with partially deuterated samples, one can distinguish between the alkyl chain and the headgroup part of the bilayers. In the gel phase, one-dimensional restricted diffusion of defects (chain orientation conserving rotational isomers) permits the perfect description of the T_1 frequency dispersion of the alkyl chains.¹⁷ The corresponding intensity function for defect diffusion is characterized by the limits

$$I_{\text{dd}}(\omega) = \begin{cases} \frac{2}{3}(\tau_b^{1/2}\tau_d^{1/2} - \tau_b) & \text{for } \omega\tau_d \ll 1 \\ \frac{\tau_d\tau_b^{1/2} - 2\tau_b\tau_d^{1/2}}{(\tau_d^{1/2} - \tau_b^{1/2})^2} \omega^{-1/2} & \text{for } \omega\tau_b \ll 1 \ll \omega\tau_d \\ \frac{\tau_d^{1/2}}{\tau_d^{1/2} - \tau_b^{1/2}} \omega^{-3/2} & \text{for } \omega\tau_b \gg 1 \end{cases} \quad (2)$$

where τ_d is the mean diffusion time across the bilayer (from headgroup to headgroup) and τ_b is the mean diffusion time over a length equal to the width of the defect.

In the liquid crystalline phase, collective modes ('director fluctuations') tend to dominate at low frequencies.¹⁸ The behavior is, however, much more complex because other mechanisms such as rotational isomerism, chain rotations, and diffusion along the curved shape of the bilayer are superimposed.

4 DEUTERON T_1 FREQUENCY DISPERSION OF PROTEIN SOLUTIONS IN D_2O

The proton signals observed in tissue, diluted aqueous biopolymer solutions, and diluted aqueous lipid bilayer dispersions tend to be dominated by water. In such systems, the polar surfaces of the macromolecular constituents are covered by hydration shells; however, these shells form only a minor fraction of the total water. Nevertheless, a strong enhancement of the spin–lattice relaxation of water occurs as first observed in protein solutions.²²

Also at a rather early stage, it was found by means of NMR spectroscopy that water molecules in the hydration shell are oriented relative to the biopolymer surface^{23,24} and congeal far below the freezing point of bulk water.²⁵ Nonfreezing water actually may be an operational definition of hydration water, the fraction of which can be quantitatively determined in this way.

Another striking finding is that translational diffusion within the hydration shells is relatively fast. Even in frozen protein solutions not far below 0°C, where diffusion is restricted to thin (about a monolayer thick) films of liquid water on the surface of the macromolecules, the diffusion coefficient is merely reduced by one order of magnitude relative to liquid bulk water.²⁶ On the other hand, orientation correlation times up to six orders of magnitude longer than those in bulk water must be concluded from T_1 frequency dispersion experiments.¹⁵

The T_1 frequency dispersion of the water phases in protein/ D_2O solutions was measured selectively using deuterium resonance.¹⁵ In the frame of the two-site fast exchange model, the effective water spin–lattice relaxation rate is given by:

$$\frac{1}{T_1} \approx \frac{1 - p_h}{T_1^f} + \frac{p_h}{T_1^h} \quad (3)$$

where T_1^f and T_1^h are the spin–lattice relaxation times in the ‘free’ (i.e. bulk) and ‘hydration’ water phases, respectively, and p_h is the fraction of hydration water.

The description of the T_1 frequency dispersion of hydration water is principally based on four competitive mechanisms:

1. Tumbling of the macromolecule including its hydration shell (correlation time τ_t).
2. Restricted rotational diffusion of water molecules about axes perpendicular to the local surface (correlation time τ_r).
3. Exchange between free and hydration water (correlation time = residence time in the hydration shell $\tau_{\perp}$).
4. Reorientations mediated by translational displacements (RMTDs) along the more or less rugged and curved surface of the macromolecule: water molecules diffuse along the surface and, as a consequence, alter their orientations which are defined by the local surface structure. The longest correlation of this mechanism is designated by $\tau_{\parallel}$.

Using the orientational structure factor formalism,²⁷ the RMTD correlation function was derived as:

$$G_{\text{RMTD}}(t) = \frac{1}{2(k_u - k_l)} \sqrt{\frac{\pi}{Dt}} [\text{erf}(\sqrt{Dt}k_u) - \text{erf}(\sqrt{Dt}k_l)] \quad (4)$$

where k_u and k_l are the upper and lower cut-off wavenumbers of the equipartition distribution assumed for the surface

Figure 3 Deuteron T_1 frequency dispersion of D_2O solutions of bovine serum albumin at 291 K. The solid lines were calculated using the RMTD formalism taking into account protein tumbling [equation (8)] and restricted rotational diffusion of the water molecules (high-frequency regime). Note that the T_1 frequency dispersions at a water content of 25 wt.% (no free water) and 50 wt.% (with free water) are qualitatively the same, apart from differences in the absolute values of the relaxation times. In these cases, the low-frequency dispersion is dominated by RMTD. At 75 wt.%, the inflection point is shifted to higher frequencies due to the competitive action of protein tumbling. (Reproduced by permission of Elsevier from R. Kimmich, W. Nusser, and T. Gneiting, *Colloids Surf.*, 1990, **45**, 283)

structure. D is the average translational water diffusion coefficient in the hydration shell. The lower cut-off wavenumber is connected with a cut-off correlation time:

$$\tau_{\parallel} = (Dk_l^2)^{-1} \quad (5)$$

revealing itself as the ‘inflection point’ $2\pi\nu\tau_{\parallel} \approx 1$ in the absence of molecular tumbling (see Figure 3). Equation (4) produces the square root frequency dependence typical for water relaxation in aqueous protein solutions at intermediate frequencies.

Restricted rotational diffusion, exchange with free water and macromolecular tumbling can be represented by exponential correlation function. Restricted rotational diffusion is only important for the high-frequency dispersion, whereas the exchange mechanism is normally too slow (relative to the other contributions) to affect the reorientation behavior. What remains as a mechanism effective in the low-frequency regime is macromolecular tumbling and RMTD.

On the basis of this scheme, the deuteron T_1 frequency dispersion of D_2O in aqueous protein solutions can be described perfectly.¹⁵ Inserting the water diffusion coefficient experimentally determined with the NMR field gradient technique, a length scale can be estimated from the RMTD correlation time $\tau_{\parallel}$ [equation (5)] revealing itself via the inflection point in the absence of macromolecular tumbling. The result is half the protein circumference, as required by RMTD.²⁷ In other words, the mean diffusion time around half the circumference of the protein molecule is calculated, on the basis of the experimental diffusion coefficient and the known short and long axes of the protein, to be of the order of 10^{-6} s, which is in perfect agreement with the inflection point measured in the absence of macromolecular tumbling.

The RMTD mechanism accounts very well for the weak temperature dependence of spin–lattice relaxation. Transient irrotational binding of a small percentage of the hydration water at certain sites, as suggested in several studies,^{22,28} would require binding energies twice as high as the apparent activation energies estimated from the experimental T_1 data. With RMTD, long correlation times are due to the geometry of the system rather than to high binding energies at certain sites. Furthermore, transient irrotational binding would result in slopes of the T_1 frequency dispersion at intermediate frequencies which are four times as high as found experimentally.

Another question is the origin of the long residence times of water molecules in the hydration shells. This, of course, is no problem, in principle, if free water is absent or frozen. Adding more and more water to a protein sample which initially has saturated hydration shells but no free water, does not change the qualitative behavior of relaxation or diffusion.^{15,26} With the exception of the onset of macromolecular tumbling (described below), there is no evidence for new relaxation mechanisms of hydration water due to the presence of free water.

The relaxation scheme outlined above can also be applied to a certain degree to systems modeling hydrated globular proteins. Water adsorbed on agglomerates of fine particles of silica of a similar diameter again shows a T_1 frequency dispersion reflecting the surface structure.³⁰

While the surfaces of fine particles of silica are expected to be smooth and chemically homogeneous, those of proteins are extremely heterogeneous with respect to polarity and hydrogen binding ability. On such surfaces water diffusion is more likely to resemble a hopping process among the preferential binding sites or areas. Translational displacements may then be governed by waiting time and step-length distributions.³¹ Nevertheless, in timescales that are long compared with typical waiting times, i.e. in the fast-jump limit, an effective diffusion coefficient can be defined. This also includes exchange processes in the sense that molecules (or hydrogen atoms) leave and reenter the hydration shell to and from other environments such as free water or sites within the protein. In this case, the surface is probed only selectively by a set of discrete binding sites. Correspondingly, the spin–lattice relaxation then originates from reorientation jumps.

From the experimental point of view, the fast jump/exchange limit reveals itself by giving monoexponential attenuation curves in diffusion as well as in spin–lattice relaxation experiments. This is what one normally observes, to a reasonably good approximation.²⁶ In this case, effective diffusion coefficients D_{eff} and effective spin–lattice relaxation times $T_{1,\text{eff}}$ can be evaluated.

The microphases (or molecular environments) can be characterized by weights p_i , diffusion coefficients D_i , and spin–lattice relaxation times $T_{1,i}$. The following exchange formulas are then valid:

$$D_{\text{eff}} = \sum_i p_i D_i \quad (6)$$

$$\frac{1}{T_{1,\text{eff}}} = \sum_i \frac{p_i}{T_{1,i}} \quad (7)$$

where $\sum_i p_i = 1$.

D_{eff} tends to be governed by environments with high molecular mobility, whereas $1/T_{1,\text{eff}}$ is dominated by the slowly reorienting molecules, that sit for relatively long periods on sites with certain orientations. Thus, high effective diffusion coefficients, long orientation correlation times, and low thermal activation energies do not contradict each other a priori.

If distributions of microphases exist, the continuous-diffusion treatment must be regarded as an approximate description of phenomena that tend to be discrete in reality. RMTD in this case probes only those sites of the surface at which spin–lattice relaxation effectively takes place (irrespective of the exchange pathways that the molecules or atoms follow in between). In principle, the applicability of the concept comprises continuous and step-by-step, surface-bound and multiphase diffusion, as long as the experiments provide *effective* diffusion coefficients and spin–lattice relaxation times.

5 CRITICAL WATER CONTENTS

In the limit of low frequencies, the T_1 frequency dispersion of water in protein solutions terminates at a certain ‘inflection frequency’ ν_i in a plateau (see Figure 2 and Figure 3). As an indication of the competitive nature of RMTD and macromolecular tumbling, this quantity depends strongly on the water content c_w (Figure 4).²⁹

Tumbling can only take place if the water content exceeds the saturation concentration c_s defined by the saturation of

Figure 4 Inflection frequency of the deuteron T_1 dispersion of BSA/D₂O solutions at 291 K versus water content. This dependence can be described by the ‘free-water volume’ model of macromolecular tumbling illustrated in the upper left-hand corner of the diagram. A protein molecule (P) including hydration water (HW) can only tumble if sufficient free water (FW) is available. The minimum free-water volume corresponds to the circumscribing sphere. Below a critical water content $c_0 \approx 65$ wt.%, macromolecular tumbling is slower than the RMTD process of water on the surface, so that the inflection frequency is governed by RMTD. Above c_0 , tumbling becomes faster than this limit. The inflection frequency is then determined by the tumbling rate of the macromolecules. The experimental data were evaluated directly from the T_1 dispersion curves, the solid line was calculated on the basis of the formalism described in the text. (Reproduced by permission of Hühlig & Wepf from R. Kimmich, *Makromol. Chem., Macromol. Symp.*, 1990, **34**, 237)

the hydration shells. In this case 'free water' is present so that, with a certain probability, a macromolecule is surrounded by enough free water for rotational jumps. The 'free-water volume' formalism¹⁵ leads to a macromolecular tumbling correlation time:

$$\tau_t = \tau_t^0 \exp \left[\gamma^* (r - 1) \frac{1 - c_w + c_s}{c_w - c_s} \right] (c_w) c_s \quad (8)$$

where $\tau_t^0 = \eta(v_p + v_s)/(k_B T)$ is the Stokes–Einstein expression for tumbling of a particle with volume $v_p + v_s$ (bare protein plus the saturated hydration shell) in a solvent with viscosity η ; $0.5 < \gamma^* < 1$ is a numerical constant; and r is the ratio of the volumes of the circumscribing sphere and the hydrated protein molecule itself approximated by an ellipsoid (see Figure 4). The critical water content c_0 at which macromolecular tumbling becomes competitive to the correlation time $\tau_{\parallel}$ corresponding to the lower cut-off wavenumber k_1 of the RMTD process, is then defined by the condition $\tau_{\parallel} = \tau_t$. From this, one finds that

$$c_0 = c_s + \frac{\tilde{\gamma}}{1 + \tilde{\gamma}} \quad (9)$$

where $\tilde{\gamma} = (r - 1)\gamma^* / \ln(\tau_{\parallel}/\tau_t^0)$. For aqueous bovine serum albumin (BSA) solutions, $c_s \approx 30$ wt.% and $c_0 \approx 65$ wt.%, that is $\tilde{\gamma} \approx 0.5$.

6 PROTON T_1 FREQUENCY DISPERSION OF TISSUE

Although water is normally the most abundant compound in tissue, and therefore provides the dominant contribution to hydrogen signals recorded in relaxation experiments, the

Figure 5 Proton T_1 frequency dispersion of a leech (in vivo) and freshly excised frog sartorius muscle (FSM) in the relaxed state in vitro. The solid lines were calculated on the basis of macromolecular tumbling, RMTD, restricted rotational diffusion of hydration water, protein backbone fluctuations and terms representing the ^{14}N – ^1H cross relaxation quadrupole dipoles. (Reproduced by permission of Elsevier from R. Kimmich, W. Nussler, and T. Gneiting, *Colloid. Surf.*, 1990, **45**, 283)

behavior observed in tissue is determined by the interaction and the cross relaxation with the macromolecular constituents. The description must therefore refer to fluctuations in the water phases as well as in the macromolecules. Assuming fast exchange between all components, it is possible to reproduce the experimental T_1 frequency dispersion of tissue by considering the combined action of RMTD in the hydration shells, tumbling and backbone fluctuations of the proteins, restricted rotational diffusion of hydration water molecules, and (with regard to the quadrupole dip frequency region) ^{14}N – ^1H cross relaxation. Figure 5 shows two representative data sets.¹⁵

Treatments of this sort are crucial for our understanding of the basic mechanisms contributing to relaxation in tissue. For the practical characterization of tissue, it may be more useful to describe the T_1 frequency dispersion by empirical intensity functions or just qualitatively. The T_1 frequency dispersion of a number of different tissues have been characterized in this way, showing significant differences.^{32–34}

7 $T_{1\rho}$ FREQUENCY DISPERSION IMAGING

The molecular motions revealing themselves in the T_1 frequency dispersion are substantial for image contrasts in

Figure 6 Cross-sectional NMR images of a mouse with an implanted tumor (left). (a) Conventional two-dimensional spin echo FT image. (b) Rotating frame dispersion image (RODI) rendering the $T_{1\rho}$ frequency dispersion as gray scale contrasts. The tumorous tissue (left) can be clearly distinguished from muscle tissue (right). (Reproduced by permission of Academic Press from E. Rommel and R. Kimmich, *Magn. Reson. Med.*, 1989, **12**, 390)

NMR tomography. At conventional magnetic flux densities, the relaxation contrasts originate from relative fast motions and represent the relaxation rates rather than the T_1 frequency dispersion. Using on- and off-resonance variants of spin–lattice relaxation in the rotating frame, an imaging sequence was proposed that gives directly the spatial distribution of the $T_{1\rho}$ frequency dispersion,^{35,36} which is indicative for slow motions, macromolecular tumbling, and RMTD.

Figure 6 shows images of a tumorous mouse recorded with this rotating frame dispersion imaging (RODI) technique and conventional tomography for comparison. Striking differences are obvious. RODI provides strong contrast of the tumorous tissue, whereas muscle tissue is suppressed. In the conventional spin echo FT image, on the other hand, both sorts of tissue are rendered with equivalent intensity. Thus biomedical applications of the low-frequency dispersion of spin–lattice relaxation suggest themselves.

1 INTRODUCTION

The nuclear Overhauser effect is defined as the change in the overall intensity of one resonance that occurs when another resonance is saturated. Generally it is expressed as the fractional enhancement:

$$f_I\{S\} = \frac{I - I^0}{I^0} \quad (1)$$

where I is the intensity of the observed resonance when the spin S is saturated and I^0 is the equilibrium intensity of the I resonance. Conventionally, the observed spin is called I and the saturated spin is called S . However, particularly for heteronuclear cases, the NOE is often also expressed as the enhancement ratio:

$$\eta = \frac{I}{I^0} = f_I\{S\} + 1 \quad (2)$$

Detection of an appreciable NOE between two spins indicates that there is a relatively short internuclear distance between them, generally less than about 4 or 5 Å. It is this through-space dependence, which is completely independent of the nature of the covalent bonding network between the two interacting spins, that makes the NOE extremely powerful for characterizing molecular stereochemistry and conformation. However, the dependence on the internuclear separation between I and S is complicated by a dependence on several other factors, particularly the rates of molecular motions. For this reason, a truly quantitative interpretation of NOE enhancements is difficult, and the effect is usually interpreted at a semiquantitative level when deriving structural information, as will be discussed below.

The original prediction by Overhauser concerning the enhancement of nuclear spin polarization in metals upon saturation of the electron spins was published in 1953,¹ and the nuclear analog was described by Solomon in 1955.² The first applications to structure determination were by Anet and Bourne in 1965,³ and for 10 years or so the method

found applications mainly in organic chemistry.⁴ Detection of NOE enhancements using repeated integration of CW-detected one-dimensional spectra imposed a detection limit in the region of 5%, but the introduction of new measurement techniques together with high-field, computer-assisted Fourier transform NMR spectrometers in the mid-1970s revolutionized the whole area. Now two experiments in particular, NOE difference spectroscopy and NOESY, have greatly improved sensitivity and allow very much more extensive use to be made of the NOE in structure determination than was possible previously. The technique is very widely used to determine stereo- and regiochemical isomerism in small and medium-sized natural and synthetic molecules, and more recently it has become the basis for a whole area of NMR, namely the structure determination of biological macromolecules, particularly proteins, in solution.⁵

2 CROSS RELAXATION AND THE ORIGIN OF THE NOE

The origin of the NOE lies in population changes caused by a particular form of longitudinal relaxation, namely dipole–dipole cross relaxation (see also *Relaxation Processes in Coupled-Spin Systems*). Longitudinal relaxation involves energy exchange events between the nuclear spin states and the ‘lattice’, which term is used to depict the continuum of translational and rotational energy levels of the system as a whole. If the population of the high-energy state of a particular nuclear spin transition is larger than its equilibrium value, it will relax back towards equilibrium through events in which individual nuclei flip from high-energy to low-energy spin state while the lattice accepts the energy released, for instance by accelerating either the overall rotation or some internal motion of the molecule in which the nuclear spin transition occurred. Similarly, if the population of the high-energy state were smaller than its equilibrium value, then corresponding decelerations of molecular motions would provide energy to promote spins to the high-energy state.

However, such relaxation events can only occur if there exists a mechanism to couple the motions of the molecule to the nuclear spin states. In practice this means that the motion must itself cause a varying transverse magnetic field at the site of the nucleus it is to relax, and that this magnetic field variation must have an appreciable frequency component corresponding to the frequency of the nuclear spin transition. In the case of dipole–dipole relaxation, this ‘local field’ originates from the magnetic dipoles of other neighboring spins. Because in this case the local field itself originates from a spin, this opens the possibility for cooperative relaxation events in which *both* spins simultaneously flip, while the lattice accepts or provides energy corresponding to the net change. This is dipole–dipole cross relaxation. The various possible transitions for the simplest case of a two-spin system are summarized in Figure 1.

Two types of cross relaxation event are possible. In one, characterized by the transition probability W_2 , both spins flip in the same sense, and the energy change accommodated by the lattice corresponds to the *sum* of the energies of the individual spin transitions. For these ‘ W_2 transitions’ to occur, the local field resulting from lattice motions must contain fluctuations

Figure 1 Energy level for a two-spin system, showing the definitions of transition probabilities (W_0 , W_1 , and W_2) and spin states ($\alpha\alpha$, $\alpha\beta$, $\beta\alpha$, and $\beta\beta$). Spin states are written with the state of I first and that of S second, i.e. $\alpha\beta$ means spin I is in the α state, and spin S in the β

at the sum frequency ($\omega_I + \omega_S$). In the other type of transition, characterized by the transition probability W_0 , the spins flip in opposite senses. In the homonuclear case, this implies that a very much smaller energy change is accommodated by the lattice, corresponding to the *difference* between the energies of the individual transitions. For ' W_0 transitions', the local field must contain fluctuations at the difference frequency ($\omega_I - \omega_S$).

These two types of cross relaxation event are crucially different in their influence on the NOE. Suppose that spin S is saturated, thereby equalizing the populations of states $\alpha\alpha$ and $\alpha\beta$, and (separately) equalizing the populations of the states $\beta\alpha$ and $\beta\beta$. For all of the relaxation transitions involving S there will now be an excess of downward transitions (i.e. high $\rightarrow$ low energy), since there are more spins in the high-energy state than would be the case at equilibrium. The excess of downward single spin flips of S (W_1 transitions) has no effect on the intensity of I . However, if spin S flips downwards during a W_2 transition, spin I also flips downwards, thereby *increasing* the population difference across the I spin transition. Thus when W_2 transitions predominate over W_0 transitions, saturation of S causes the intensity of I to increase, which corresponds to a positive NOE enhancement. Conversely, for a W_0 transition, if spin S flips downwards then spin I must flip upwards, thereby *decreasing* the population difference across the I spin transitions. Therefore if W_0 transitions predominate over W_2 transitions, saturation of S causes the intensity of I to decrease, implying a negative NOE enhancement. If there are equal numbers of W_2 and W_0 transitions, the opposing effects cancel and there is no NOE at all.

2.1 The NOE for an Isolated Two-Spin System

These points may be expressed more formally using the Solomon equations, which form the basis for the theory of the NOE. For a system of two isolated spins $\frac{1}{2}$, the equation of

motion for the longitudinal component of I spin magnetization is given by^{2,6}

$$\frac{dI_z}{dt} = -(I_z - I_z^0)(W_{0IS} + 2W_{1I} + W_{2IS}) - (S_z - S_z^0)(W_{2IS} - W_{0IS}) \quad (3)$$

If S is saturated until steady state is reached, then dI_z/dt and S_z may both be set to zero, whereupon rearrangement and substituting $I_z^0 = (\gamma_I/\gamma_S)S_z^0$ gives

$$f_I\{S\} = \frac{I_z - I_z^0}{I_z^0} = \frac{\gamma_S}{\gamma_I} \frac{W_{2IS} - W_{0IS}}{W_{0IS} + 2W_{1I} + W_{2IS}} \quad (\text{two-spin}) \quad (4)$$

where $f_I\{S\}$ is the fractional steady state NOE enhancement measured at I upon completely saturating S . For the case of two spins $\frac{1}{2}$ relaxing exclusively via their mutual dipole-dipole interaction, the values of the various transition probabilities can be shown to be⁷

$$\left. \begin{aligned} W_{0IS} &= \frac{1}{20} K^2 J(\omega_I - \omega_S) \\ W_{1I} &= \frac{3}{40} K^2 J(\omega_I) \\ W_{2IS} &= \frac{3}{10} K^2 J(\omega_I + \omega_S) \end{aligned} \right\} \left(\begin{array}{l} \text{dipole} \\ \text{only,} \\ \text{extreme} \\ \text{narrowing} \end{array} \right) \quad (5)$$

where $K = (\mu_0/4\pi)\hbar\gamma_I\gamma_S r_{IS}^{-3}$. Given that K always appears as its square, this shows that all of these intramolecular dipole-dipole transition probabilities depend linearly on the minus sixth power of the internuclear distance r_{IS} . The various spectral density functions $J(\omega_x)$ each describe the power available at the corresponding frequency ω_x from molecular motions to stimulate relaxation. These spectral density functions provide the vital link between transition probabilities and molecular tumbling properties. If it is assumed that molecular tumbling is isotropic, and that it can be described by a correlation function that is a simple exponential decay with a rate constant τ_c , then the spectral density functions are given by

$$J(\omega_x) = \frac{2\tau_c}{(1 + \omega_x^2 \tau_c^2)} \quad (6)$$

For small molecules molecular tumbling is very rapid, τ_c is very short and $\omega_x \tau_c < 1$. This is called the 'extreme narrowing' condition, and in this limit the denominators of the various spectral density expressions can all be set to unity, leading to much simpler expressions for the transition probabilities in equation (5). When these are substituted into equation (4), we have

$$\begin{aligned} f_I\{S\} &= \frac{\gamma_S}{\gamma_I} \frac{\frac{3}{5} K^2 \tau_c - \frac{1}{10} K^2 \tau_c}{\frac{1}{10} K^2 \tau_c + \frac{3}{10} K^2 \tau_c + \frac{3}{5} K^2 \tau_c} \\ &= \frac{\gamma_S}{2\gamma_I} \left(\begin{array}{l} \text{two-spin} \\ \text{dipole only,} \\ \text{extreme} \\ \text{narrowing} \end{array} \right) \end{aligned} \quad (7)$$

which, in the homonuclear case, is just +50%.

As molecular weight increases and tumbling becomes slower, the spectrum of rates of molecular motions becomes

more and more concentrated at low frequencies. The spectral densities $J(\omega_I + \omega_S)$ and $J(\omega_I)$ thus become progressively smaller until they cease to make any significant contribution to relaxation; in other words, the local field produced by motions of neighboring dipoles in large molecules has no frequency component high enough to stimulate W_2 or W_1 transitions. In heteronuclear systems, the same fate eventually overtakes $J(\omega_I - \omega_S)$ also [indeed, if γ_S and γ_I have opposite signs, $J(\omega_I + \omega_S)$ will diminish before $J(\omega_I - \omega_S)$, and for $S = {}^1\text{H}$, ω_I is generally smaller than $(\omega_I - \omega_S)$ or $(\omega_I + \omega_S)$], but in homonuclear cases the difference frequency $(\omega_I - \omega_S)$ is so low (being just a difference of chemical shifts in this case) that $J(\omega_I - \omega_S)$ always remains large.

Thus, although in the extreme narrowing limit there are six times as many W_2 transitions as W_0 transitions, where $\omega\tau_c \approx 1$ (for a homonuclear system) the numbers of W_2 and W_0 transitions are nearly equal, resulting in small or zero NOE enhancements irrespective of the internuclear distances involved. For homonuclear systems in still larger molecules where $\omega\tau_c \gg 1$, all the spectral densities other than $J(\omega_I - \omega_S)$ become insignificant, dipolar relaxation is completely dominated by W_0 transitions and NOE enhancements are all negative. This limit is known as the ‘spin diffusion’ limit, for reasons that will become apparent shortly.

The overall dependence of the NOE on $\omega_I\tau_c$ for an ideal two-spin system relaxing exclusively through mutual dipole–dipole interactions can be calculated from equations (4)–(6). This function, often called $\eta_{\max}$, is actually *independent* of the internuclear distance r , since all of the terms in equation (4) have an identical dependence on r^{-6} that cancels out. Conceptually, $\eta_{\max}$ represents the theoretical maximum NOE enhancement observable between two spins in the absence of other spins and external relaxation. Figure 2 shows $\eta_{\max}$ for a homonuclear system.

To simplify later equations, it is convenient to introduce here the cross-relaxation rate σ_{IS} and the direct relaxation rate ρ_{IS} , defined by

$$\sigma_{IS} = W_{2IS} - W_{0IS}; \quad \rho_{IS} = W_{0IS} + 2W_{1I} + W_{2IS} \quad (8)$$

Figure 2 Maximum theoretical homonuclear NOE enhancement ($\eta_{\max}$) for a two-spin system relaxing exclusively via dipolar interaction, as a function of $\omega\tau_c$. For small rapidly tumbling molecules where $\omega\tau_c \ll 1$, the maximum NOE enhancement is +50%, while for large, slowly tumbling molecules where $\omega\tau_c \gg 1$, the maximum enhancement is –100%

In this way, $\eta_{\max}$ can be reexpressed as

$$\eta_{\max} = \frac{\gamma_S}{\gamma_I} \frac{\sigma_{IS}}{\rho_{IS}} \quad (9)$$

2.2 Competition from Other Relaxation Mechanisms

Of course, in real situations, there will be relaxation mechanisms other than intramolecular dipole–dipole operating, and there will generally be more than two spins in the system. Almost without exception, other relaxation mechanisms do not contribute to cross relaxation at all, so their only influence is to dilute the contribution of dipolar relaxation to the whole. Such additional relaxation is often referred to as ‘leakage’, and in the equations the ‘leakage rate’ ρ^*_I is introduced as a *purely empirical* correction factor to allow for it; the subscript I is required since, in principle, every spin could have a different leakage rate.

$$f_I\{S\} = \frac{\gamma_S}{\gamma_I} \frac{\sigma_{IS}}{\rho_{IS} + \rho^*_I} \quad (\text{two-spin}) \quad (10)$$

Significantly, for most systems leakage is much more important for small molecules than for large. This is because dipolar relaxation becomes steadily more efficient as tumbling rates diminish, whereas the leakage rate is often not greatly affected by solute tumbling rate. For instance, in many cases the dominant source of leakage is intermolecular dipole–dipole interactions between spins on the solute and unpaired electrons of dissolved oxygen molecules (see also **Paramagnetic Relaxation in Solution**). This interaction is likely to be largely independent of solute tumbling rate, since the relative positions of the electron and nuclear spins will always vary rapidly as the oxygen molecule tumbles. Figure 3 shows how the ideal homonuclear two-spin NOE $\eta_{\max}$ is reduced more severely for small molecules than for large, assuming various constant leakage rates.

For spin systems involving nuclei with $I > \frac{1}{2}$, efficient quadrupolar relaxation usually leads to very high leakage rates,

Figure 3 Reduction in $\eta_{\max}$ resulting from leakage, e.g. due to intermolecular relaxation by dissolved oxygen. The different curves are calculated according to equation (10) using the indicated values for ρ^*_I , assumed to remain constant as a function of solute tumbling rate, and taking an internuclear distance r_{IS} of 2 Å and a spectrometer frequency of 300 MHz

so that little or no NOE is detectable (see also *Relaxation of Quadrupolar Nuclei Measured via Multiple Quantum Filtration*).

3 MULTISPIN SYSTEMS

In multispin systems, two further points need to be considered. Firstly, spin I will be relaxed not only by spin S but also potentially by all the other spins in the system (here collectively denoted X), depending on their distances from I . This adds further terms to the direct relaxation rate of I , diluting the NOE in much the same way as does ρ_I^* . Thus, the total relaxation rate of I becomes

$$R_I = \rho_{IS} + \sum_X \rho_{IX} + \rho_I^* \quad (11)$$

Note that there is an implicit assumption made in equation (11) and in all the theory for multispin NOE enhancements that follows, namely that the total relaxation behavior of the system can be obtained by a simple summation over all possible pairwise interactions. This amounts to neglecting the cross correlation that must exist between the random motions of one spin pair and another within the same molecule. This assumption is almost universally made throughout applications of the NOE, and various authors have shown that it actually introduces little error into conventional interpretations (see also *Relaxation Processes: Cross Correlation and Interference Terms*).⁸

Note also that the inclusion of ρ_I^* in this definition implies that R_I corresponds to the reciprocal of the *experimentally measured* selective T_1 . In all the equations involving R_I that follow, one may in principle either include or exclude ρ_I^* . If it is included, the equations relate directly to measured results, but they require that measured values or at least estimates of leakage rates are available. If ρ_I^* is excluded, the equations relate to a hypothetical spin system with no leakage, allowing idealized NOE properties to be calculated provided only that the relevant internuclear distances are known.

The second important point for the NOE in multispin systems is the possibility of indirect enhancements. Once spins close to S have themselves received NOE enhancements, their own populations are no longer at equilibrium. This in turn disturbs the balance of their cross relaxation with their own neighboring spins, thereby creating additional NOE enhancements often called *indirect* enhancements. Such indirect enhancements can themselves cause further enhancements, and so on, until at steady state the original population disturbance at S may cause intensity changes to a greater or lesser extent throughout the spin system. For a multispin system, the relevant Solomon equation is

$$\begin{aligned} \frac{dI_z}{dt} = & -(I_z - I_z^0)(W_{0IS} + 2W_{1I} + W_{2IS}) - (S_z - S_z^0) \\ & \times (W_{2IS} - W_{0IS}) - \sum_X (X_z - X_z^0) \\ & \times (W_{2IX} - W_{0IX}) \end{aligned} \quad (12)$$

Setting dI_z/dt and S_z to zero as before, then rearranging and substituting $I_z^0 = (\gamma_I/\gamma_S)S_z^0 = (\gamma_I/\gamma_X)X_z^0$ gives the steady

state enhancement as

$$f_I\{S\} = \frac{\gamma_S}{\gamma_I} \frac{1}{R_I} \left[\sigma_{IS} - \sum_X \frac{\gamma_X}{\gamma_S} f_X\{S\} \sigma_{IX} \right] \quad (13)$$

where all the indirect contributions to $f_I\{S\}$ are represented by the summation over the other spins X . Thus, in general, the theoretical steady state enhancements (i.e. assuming no leakage) upon saturating S in an N -spin system where the distances are all known can be calculated from a set of $(N - 1)$ linear simultaneous equations of the form of equation (12).⁹ Note particularly that steady state enhancements are not controlled only by the internuclear distance between I and S , but are a function of many (potentially all) of the internuclear distances in the system. This crucially important point is all too often ignored in naïve interpretations of NOE experiments, particularly those involving small molecules.

The significance of indirect enhancements depends very much on the tumbling rate of the molecule under study, as will be illustrated in the following sections.

4 STEADY-STATE NOE EXPERIMENTS WITH SMALL MOLECULES

For homonuclear systems in small molecules, direct enhancements are positive, so that a directly enhanced signal can itself be thought of as being ‘negatively saturated’. Spins that are significantly closer to such a directly enhanced spin than they are to the saturated spin therefore receive a *negative* enhancement from the directly enhanced spin, often called a ‘three-spin effect’. However, at extreme narrowing, σ is significantly smaller than R_I , so that the transmission of enhancements down a chain of spins is a relatively inefficient process, even in the absence of leakage. In practice, efficient leakage reduces the transmission of indirect effects still further, and effects transmitted over more than one intermediate spin are almost never observed in small molecules. Given the sign distinction between direct and three-spin effects, this makes distinguishing indirect effects a relatively trivial matter.

Clearly, the geometry of a spin system is crucial in determining what effects will actually be seen. Substantial three-spin effects are generally associated with spins in a nearly linear arrangement, and it also follows that for some arrangements of spins, appreciable direct and indirect effects cancel leaving a small or zero net enhancement despite a short IS internuclear distance. These points are illustrated by the theoretical enhancements shown for some particular geometries in Figure 4.

4.1 NOE Difference Spectroscopy

The experiment that is now most widely used to measure steady state enhancements in small molecules is the NOE difference experiment, the pulse sequence for which is summarized in Figure 5. Two datasets are acquired, in one of which selective, low-power preirradiation is applied to the target resonance S . In the other experiment (the control), all details are identical to the first except that the preirradiation is applied in a blank area of the spectrum. Subtraction of

Figure 4 Theoretical NOE intensities ($\rho^*_I = 0$) for various simple multispin systems at the extreme narrowing limit ($\omega\tau_c \ll 1$). (a) Illustration of the transmission of a three-spin effect (here $f_X\{S\}$) in a linear spin system. (b) Illustration of how substantial direct and indirect contributions can cancel, leaving a very small net enhancement ($f_X\{S\}$) despite short distances. (c) Illustration as to how two direct effects corresponding to the same distance can differ drastically when one enhanced spin is rapidly relaxed by another near neighbor, and the other enhanced spin is not

Figure 5 Pulse sequence for the one-dimensional NOE difference experiment

the control spectrum from that in which S is preirradiated yields a difference spectrum containing only those signals that changed intensity upon preirradiation of S . Note that, since the saturating field is switched off during acquisition of the FID, no coherent decoupling effects are present to complicate the data, and (ideally) only population effects can contribute to the difference spectrum.

In order to minimize unwanted differences between the datasets arising from instrumental instabilities, acquisition of the two datasets is usually carried out in an interleaved manner. If, as is usual, a series of experiments is to be carried out, a list is constructed of frequencies corresponding to the various preirradiation targets. Since, in principle, the control data are identical for all the different preirradiation targets, generally only one or two control entries are included in this list. The spectrometer then cycles repeatedly through the whole list, typically acquiring two or four dummy scans followed by eight or 16 transients at each frequency on each pass, until the available experimental time has been filled. A separate dataset is maintained for each preirradiation frequency, and incoming data are always added to data acquired at the same frequency on previous cycles. Careful attention to temperature equilibration and stability are also crucial to obtaining high-quality data. Long preirradiation periods (5–10 s or more) are often useful in NOE difference experiments, since then informative three-spin effects are

allowed to become significant. However, when sensitivity for measuring relatively strong direct effects is the only issue, somewhat shorter preirradiation periods of $(1-3)T_1$ are often used in conjunction with an increased number of scans. Note also that there is no need whatsoever for a relaxation delay between acquisition and the start of the next preirradiation.

Preirradiation power is generally set extremely low, in order to avoid unwanted saturation of neighboring resonances. This can result in the target resonance being only partially saturated, which leads to NOE enhancements being only partially excited in direct proportion. However, this is of little real consequence since the absolute size of the enhancement rarely needs to be interpreted quantitatively in steady state experiments, the only real loss being one of sensitivity. Various techniques are available for saturating multiplets evenly without using high powers, for instance by cycling the preirradiation frequency around the multiplet components during each preirradiation period. These methods help to minimize the unwanted effects of selective population transfer (SPT) that arise at scalar coupling partners of the irradiated signal if the multiplet components of S are unevenly saturated (e.g. see Figure 6); these appear as intense antiphase signals at the coupled signals, and are completely unrelated to the NOE. Further suppression of SPT effects can be achieved by using a composite 90° pulse to excite the spectrum.

With care and long acquisition periods, enhancements well below the 1% level may now be quite routinely detected using

Figure 6 NOE difference and control spectra of a mixture of 4- and 9-methylcyclopenta[*b*]naphthalenes [compounds (1) and (2), obtained by photolysis of 4a-methyl-4aH-fluorene followed by treatment with butyllithium] in CDCl₃ solution, recorded at ambient temperature and 250 MHz (preirradiation period 5 s).¹¹ For each NOE difference trace, the preirradiation target is indicated on the left, and the relative vertical scaling on the right. The enhancements between the CH₂ and CH₃ signals in compound (1), and the enhancements H₉{CH₂} and H₃{CH₃} in compound (2), established the relative assignment of signals from the two isomers, thereby allowing compound (1) to be identified as the one that was initially formed in the photolysis step (the small peaks near 2.9 ppm and 3.9 ppm are due to impurities). This example also demonstrates the use of NOE difference experiments in analyzing mixtures in cases where spectral overlap is not too severe, and the appearance of SPT artifacts at coupling partners of the preirradiated signals (these spectra were recorded before the methods of SPT suppression referred to in the text had been introduced). Adapted with permission from Neuhaus¹¹

the NOE difference technique (but such experiments are a particularly demanding test of instrumental stability).¹⁰

4.2 Applications to Small Molecules

One-dimensional NOE difference spectroscopy has now become an essential and routine tool for the determination of regio- and stereochemical isomerism in small and medium-sized molecules. However, a major and unavoidable limitation to the approach is imposed by molecular flexibility. The NOE can only distinguish between two or more possible structures or conformations if there is some significant and *consistently maintained* difference between internuclear distances corresponding to measurable NOE enhancements in the various cases. In this context, it is largely irrelevant whether the formal difference between the possibilities is one of covalently bonded structure or one of noncovalently stabilized conformation, provided that the relative spatial arrangement of protons is preserved.

Some of the simplest applications of the NOE involve the determination of aromatic ring and olefinic double-bond substitution patterns. Interpretation of the NOE enhancements in these essentially flat molecules is particularly simple, since the differences between internuclear distances in various possible structures are usually extremely clear cut. Aromatic ring fusion patterns are also usually quite straightforward to establish, provided, as in the case of substitution patterns, that there are strategically located protons at or near the sites that differ between the structures needing be distinguished (e.g. on each side of ring junctions). A simple example is shown in Figure 6.

Saturated systems often require a somewhat more sophisticated analysis, since differences between internuclear distances in various structures may be more subtle, and the importance of relaxation from other nearby protons in determining the relative sizes of enhancements may be less obvious. Substitution positions and ring fusion patterns are more likely to be available from coupling connectivities in such cases, so it is more often *stereochemical* information that is required

from the interpretation of the NOE results. Applications to five-membered rings are perhaps more common than to six-membered rings, presumably due to the relative difficulty of using coupling constant magnitudes to distinguish whether protons are *cis* or *trans* in a five-membered ring. Rigidity is again crucial to the successful application of the technique, so applications to medium-sized or larger ring systems are more difficult, unless flexibility is limited, e.g. by fusion to another ring.

In larger systems, rigidity may be maintained in more complicated ways, e.g. by a specific, intramolecular network of hydrogen bonds that may, in effect, convert an acyclic portion of a molecule into a cyclic one. In combination with other NMR techniques, the NOE has been used to define largely or completely the stereochemistry and conformation of many complicated natural products, including steroids and other terpenoids, alkaloids, saccharides, small cyclic peptides, and various other types of natural macrocycles (see also *Carbohydrates and Glycoconjugates*).¹⁵

Applications to characterizing conformational equilibria have been much less common. Accurate quantitation and very careful analysis are essential, and several unavoidable assumptions render analysis of even the simplest systems extremely approximate. In particular, if averaged NOE data from a rapidly exchanging system are to be fitted to try to find the relative proportions of two or more conformers, then the r^{-6} dependence of enhancements implies that the fit will be critically dependent on having very accurate internuclear distances available from models of the contributing conformers. The outlook for improvement in this situation remains bleak.

A few representative examples of applications of the NOE to problems of structure determination in small and medium-sized molecules are summarized in Figure 7.

5 KINETIC NOE EXPERIMENTS WITH LARGE MOLECULES

In complete contrast to the situation for small molecules, for homonuclear experiments with large molecules direct and

Figure 7 A few representative examples of structural applications of the NOE in small molecules. Compound (3) is a petroporphyrin whose substitution pattern was determined by the NOE enhancements shown.¹² Compound (4) is a hydroxyhomocepham isolated during work on penicillin biosynthesis, in which the stereochemistry at C-3 was established by the enhancements shown.¹³ Compound (5) is a benzylisoquinoline alkaloid called misramine, the structure of which was established by a combination of spectroscopic techniques, and including the NOE enhancements shown.¹⁴ In this case the enhancement data helped to link together partial ^1H spin systems determined by decoupling experiments, to determine the stereochemistry, and to determine that the site of the acetal function was C-11 rather than C-9

indirect enhancements are all negative, and the predominance of W_0 transitions over all others means that indirect enhancements can be transmitted efficiently down a chain of spins. In the limit of slow tumbling, saturation of any spin in a homonuclear multispin system will, at steady state, cause a -100% enhancement of every other spin; in other words, the entire spectrum will become saturated and disappear. This is the ultimate demonstration of the process known as 'spin diffusion', whereby enhancements in large molecules lose their specificity by dissipating onto other nearby spins.

Spin diffusion renders steady state homonuclear experiments on large molecules completely useless in terms of determining structures. Even limited spin diffusion poses a severe problem for interpretation, since direct and indirect enhancements cannot be distinguished a priori, being all negative, making it impossible to equate a given strength of enhancement with a given distance even approximately. In order to overcome this problem, NOE enhancements for such molecules are measured not at steady state but rather during the early stages of their build up.

Two types of simple kinetic experiment are possible. In the first, generally called the truncated driven Overhauser experiment or TOE, the NOE is driven by continuous saturation of the S signal throughout a short, variable period of NOE evolution. This experiment is essentially identical to the NOE difference experiment, except that the period of preirradiation during which the NOE evolves is kept much shorter. In the second type of kinetic experiment, perturbation of the S spin populations is achieved effectively instantaneously using pulses, and the NOE is then allowed to evolve for a short variable period in the absence of saturation. Experiments in this latter category include the two-dimensional NOESY experiment (see *NOESY*) and all its variants (see also *Homonuclear Three-Dimensional NMR of Biomolecules*), and also various transient one-dimensional experiments based on allowing the NOE to evolve after a selective inversion pulse to the signal corresponding to S (note, however, that there can be no true two-dimensional analog of the steady state or TOE experiments).

The period of NOE evolution in any kinetic experiment is generally called the mixing time, or τ_m . Provided that τ_m is sufficiently short, direct enhancements never become large enough to cause substantial indirect enhancements, and the process of spin diffusion has no chance to begin. This limit is known as the 'initial rate approximation'. The limiting form of equation (12) at short times may be found by substituting $S_z = 0$, $I_z = I_z^0$, and $X_z = X_z^0$, leaving

$$\left. \frac{dI_z}{dt} \right|_{t=0} = \sigma_{IS} S_z^0 \quad (14)$$

(for experiments where S is selectively inverted rather than saturated, the appropriate initial condition is $S_z = -S_z^0$, leading to an initial rate of $2\sigma_{IS} S_z^0$).

Thus the initial rate of NOE buildup is directly proportional to σ_{IS} , and therefore also to r^{-6} . It is this simple proportionality that forms the basis for most uses of the NOE in the structure determination of large molecules. At later times, once an appreciable enhancement has built up at I , then relaxation of the I spins at a rate determined by R_I starts significantly to oppose the buildup of the enhancement, and the steady state represents the balance that is eventually reached between these

processes and also the influence of indirect enhancements. This also shows that the period of validity of the initial rate approximation depends on R_I , and may thus be different for different spins. However, broadly speaking, it is the molecular tumbling rate that is the main factor that determines how short mixing times must be if the direct proportionality between NOE intensity and r^{-6} is to be at least approximately preserved; the more slowly the solute tumbles, the faster longitudinal relaxation will occur and the shorter the validity of the initial rate approximation will last.

Although most interpretation of NOESY data and other kinetic NOE experiments is based on the assumption (or hope) that the initial rate approximation is still valid at the particular values of τ_m used, it is also possible to calculate the whole time-course for the evolution of NOE enhancements in multispin systems of known geometry. The relaxation behavior of a multispin system can be fully described in terms of the relaxation matrix $\mathbf{R}$, defined by

$$\mathbf{R} = \begin{bmatrix} R_1 & \sigma_{12} & \sigma_{13} & \cdots & \sigma_{1N} \\ \sigma_{21} & R_2 & \sigma_{23} & \cdots & \sigma_{2N} \\ \sigma_{31} & \sigma_{32} & R_3 & \cdots & \sigma_{3N} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \sigma_{N1} & \sigma_{N2} & \sigma_{N3} & \cdots & R_N \end{bmatrix} \quad (15)$$

The intensities of the NOESY cross peaks at time τ_m are then given by:

$$\mathbf{a}(\tau_m) = \exp(-\mathbf{R}\tau_m) \mathbf{a}(0) = \mathbf{T} \exp(-\mathbf{D}\tau_m) \mathbf{T}^{-1} \mathbf{a}(0) \quad (16)$$

where $\mathbf{a}(\tau_m)$ is the matrix of cross peak intensities at mixing time τ_m , $\mathbf{a}(0)$ is the corresponding matrix at zero mixing time, $\mathbf{D}$ is the diagonal matrix comprised of the eigenvalues of $\mathbf{R}$, and $\mathbf{T}$ is the matrix comprised of the eigenvectors of $\mathbf{R}$. The matrix $\mathbf{a}(0)$ is of course diagonal, and is needed only for normalization. Figure 8 shows how the intensities of the cross peaks and diagonal peaks in the NOESY spectrum vary as a function of τ_m , for a two-spin system in the extreme narrowing limit, and for one near the spin diffusion limit.

Figure 8 Simulated time course for cross-peak and diagonal peak intensity in a NOESY experiment for an isolated two-spin homonuclear system, as a function of mixing time (τ_m) for two different motional regimes. In a rapidly tumbling molecule ($\omega\tau_c \ll 1$) the cross peak is negative relative to the diagonal, and builds up and decays slowly, whereas for a slowly tumbling molecule ($\omega\tau_c \gg 1$) the cross peak is positive and builds up rapidly before decaying slowly

A slightly more complicated matrix equation also exists for describing the time-course of TOE experiments:

$$\mathbf{f} = [\mathbf{R}'^{-1} \sigma] - [\mathbf{T}' \exp(-\mathbf{D}' \tau_m) \mathbf{T}'^{-1} \mathbf{R}'^{-1} \sigma] \quad (17)$$

where $\mathbf{f}$ is the column matrix of enhancements $f_I\{S\}$, σ is the column matrix of cross-relaxation rates involving S , and $\mathbf{R}'$, $\mathbf{T}'$, and $\mathbf{D}'$ are matrices analogous to $\mathbf{R}$, $\mathbf{T}$, and $\mathbf{D}$ in equation (16), but reduced by the elimination of all entries involving spin S . In addition to these matrix formulations, there are iterative numerical approaches to calculating the time course of NOESY and TOE experiments.^{16,17}

At a practical level, if quantitative intensities are required for estimating internuclear distances, it is important that the spin populations be at equilibrium at the start of each pass through the pulse sequence. This is one reason why such kinetic experiments are used mainly for large molecules; for small molecules, this condition implies that long relaxation delays (tens of seconds) are required, making overall experiment times very long.

5.1 Applications to Biological Macromolecules

Generally, structure determinations of biological macromolecules rely on the assignment and classification of a large number of NOESY cross peaks linking individual spin pairs, followed by the calculation of a family of structures consistent with these data. Methods for assigning such spectra are discussed elsewhere.¹⁸ The simple interpretation of data derived from NOESY spectra is usually based on an assumed validity of the initial rate approximation, so that the intensities of individual cross peaks are identified exclusively with the corresponding internuclear distance. In this context, this approximation is often known as the 'isolated spin-pair approximation', or ISPA. Cross peaks are classified semiquantitatively into groups such as 'strong', 'medium', and 'weak', and each category is interpreted as corresponding to a particular range of internuclear distances, following calibration by comparison with cross peaks corresponding to known distances. Usually, only the upper bound of each distance range is defined by the NOE intensity, in order to allow for the possibility that enhancements due to spins that are actually close together are made weaker by internal motions.

Various types of computer program are then used to generate a structure from the NMR data in conjunction with the known covalent connectivity and ideal covalent geometry. Although the bulk of the NMR data comprise NOE-derived distance constraints, it is common also to use torsion angle constraints derived from scalar coupling constant measurements and hydrogen bonding constraints derived from identification of slowly exchanging NH protons. Methods used for calculating biological macromolecular structures include distance-geometry, simulated annealing, and restrained molecular dynamics calculations, and also probabilistic model-building approaches; details may be found elsewhere (see also *Distance Geometry*).¹⁹ Normally an ensemble of calculations is run with each member starting from a randomly different set of initial conditions. Comparing the structures by superposition identifies which regions are well defined by the data, since only such regions are conserved across the ensemble.

Full matrix calculations of the NOE intensities can also be used to refine structures based on ISPA calculations, since they allow at least limited spin-diffusion to be accounted for explicitly (see *Protein Structures: Relaxation Matrix Refinement*). Although equation (16) allows the prediction of NOE intensities at any point during their evolution for a known structure, the reverse process, calculation of all the internuclear distances directly from the NOE intensities, would require that the *complete* NOESY intensity matrix be known, including all of the diagonal elements. Given that, in practice, such complete information is never available for complicated spectra of macromolecules, various iterative approaches have been developed that improve the fit of a starting structure to the available NOE data, either by progressively modifying the structure (e.g. the program IRMA²⁰), or by iterating on the internuclear distances themselves (e.g. the program MARDIGRAS²¹).

The whole field of application of the NOE to macromolecules has seen a huge growth since the first three-dimensional protein structure derived from NMR (that of BUSI-III) was published by Williamson et al. in 1986.²² The size of proteins that can be tackled is limited principally by the assignment problem, both in terms of assigning all the ¹H chemical shifts within the protein, and in terms of assigning each individual NOE cross peak; the latter becomes a severe problem in its own right for proteins that exhibit extensive chemical shift degeneracy. The homonuclear experiments used for making assignments in unlabeled proteins begin to fail when ¹H linewidths become significantly greater than the values of typical (¹H,¹H) coupling constants, implying that for nonaggregated globular proteins this methodology is usually applicable up to polypeptide chain lengths of a little over 100 residues (see also *Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*).¹⁸

More recently, it has become practical to obtain protein samples in which all (<98%) carbon atoms are isotopically substituted with ¹³C, and all nitrogens with ¹⁵N; this is achieved by overexpression of the protein in a bacterial system growing in an appropriately isotopically enriched medium. This has opened the door to a whole barrage of new NMR techniques for the assignment of signals and NOE cross peaks, the details of which may be found elsewhere (see also *Half-Filter Experiments: Proton-Carbon-13; Three- and Four-Dimensional Heteronuclear Magnetic Resonance; Three-Dimensional HMQC-NOESY, NOESY-HMQC, and NOESY-HSQC*).²³ These make use of the much larger one-bond heteronuclear and (¹³C,¹³C) couplings to detect through-bond connectivities and disperse crowded spectra in three or four frequency dimensions. It is not really clear yet what the upper size limit is for studying such isotopically enriched proteins, but systems approaching 200 residues have already been solved and it seems likely that larger ones will follow.

Although perhaps the most spectacular results have been obtained with proteins, related studies for DNA oligonucleotides have yielded much structural information,²⁴ although reliable identification of sequence-dependent conformation of double-helical DNA has proved somewhat elusive due to the essentially linear nature of the DNA molecule (see *DNA Triplexes, Quadruplexes, and Aptamers; DNA: A-, B-, and Z-; Nucleic Acid Structures in Solution: Sequence Dependence; Nucleic Acids: Spectra, Structures, and Dynamics*). Very

recently, NOE-based structure determinations of small RNA molecules have been reported, some making use of global isotopic labeling in a similar fashion to that used for proteins,²⁵ and the first solution structures of protein–nucleic acid complexes are now beginning to appear.²⁶

6 THE ROTATING FRAME NOE

As Figure 2 makes clear, for homonuclear spin systems where $\omega\tau_c \approx 1$, all conventional NOE enhancements are small or zero, irrespective of the internuclear distances involved, representing a severe problem for studies of intermediate-sized molecules. However, this problem can be avoided by carrying out a different type of NOE experiment, in which NOE enhancements evolve not between elements of longitudinal magnetization as in the conventional experiment, but rather between elements of transverse magnetization during a period of spin locking.

Spin locking suppresses the *relative* precession of chemically shifted resonances within the spectrum; in other words, while the spin locking field is switched on, all the transverse magnetization components from the different signals in the spectrum precess *together*, with a constant relative phase. The simplest spin locking sequence comprises a hard 90° pulse followed by application of a spin locking field 90° out of phase with the pulse. If, prior to the 90° pulse, the system is prepared by inverting a particular signal S , then transverse cross relaxation during the spin locking period will lead to a transient rotating frame Overhauser effect, accumulating at signals corresponding to the cross-relaxation partners of S . This is exactly analogous to a conventional one-dimensional transient NOE experiment, in which the S signal is inverted prior to a period for evolution of longitudinal NOE enhancements. The role of the spin locking field is perhaps best viewed as maintaining a constant phase relationship between the inverted signal and the others; had the spin locking field been absent, relative precession due to chemical shifts would have prevented any *net* accumulation of enhancement. Most commonly, ROE enhancements are measured using the two-dimensional ROESY experiment, which is the ROE analog of NOESY (see **ROESY**). Note that since there is no frequency difference between any of the spins while the ROE enhancements are evolving during the spin locking period, it is not possible to saturate selectively any of them separately during this time. There can therefore be no ROE analog of the conventional steady-state experiment.

The reason why ROE experiments differ fundamentally from longitudinal ones is that the transition probabilities for spin locked dipolar relaxation are based on different spectral densities. The transverse cross-relaxation rate σ_2 and transverse direct relaxation rate ρ_2 are given by²⁷

$$\sigma_2 = \frac{1}{40}K^2[\frac{9}{2}J(2\omega_1) - \frac{1}{2}J(0) + 6J(\omega_0)] \quad (18)$$

$$\rho_2 = \frac{1}{40}K^2[\frac{9}{2}J(2\omega_1) + \frac{1}{2}J(0) + 9J(\omega_0) + 6J(2\omega_0)] \quad (19)$$

where ω_0 is the Larmor frequency and ω_1 is the frequency of precession about the B_1 field. For comparison, the equivalent expressions for their longitudinal counterparts, obtained by substituting into equation (8), are

$$\sigma_1 = \frac{1}{20}K^2[-J(\omega_I - \omega_S) + 6J(2\omega_0)] \quad (20)$$

$$\rho_1 = \frac{1}{20}K^2[J(\omega_I - \omega_S) + 3J(\omega_0) + 6J(2\omega_0)] \quad (21)$$

Note that for slowly tumbling molecules where terms in $J(\omega_0)$ and $J(2\omega_0)$ are insignificant, σ_2 is twice σ_1 . If NOESY and ROESY data are to be compared directly in such cases, τ_m should therefore be set twice as long in the NOESY experiment as in the ROESY.

The key difference between these expressions is that, unlike σ_1 , σ_2 cannot become negative unless the extreme narrowing approximation breaks down *with respect to* ω_1 . Typical spin locking field strengths in ROE experiments are between about $\omega_1 = 2$ kHz and $\omega_1 = 10$ kHz, implying that molecular motions in liquid samples will never be significantly slower than this so that direct ROE enhancements are always positive. Another key difference to the conventional experiment concerns spin diffusion. In effect, any size of molecule behaves in an ROE experiment as though it were a small molecule in a conventional NOE experiment (hence the original acronym CAMELSPIN for the experiment;²⁸ this stands for cross relaxation appropriate for mini-molecules emulated by spin locking). Thus, there is an alternation of sign for each intermediate spin over which an indirect enhancement is transmitted, and the transmission of indirect effects is relatively inefficient due to the loss that occurs at each step. For a large molecule, the influence of spin diffusion is markedly reduced in an ROE experiment relative to the corresponding NOE experiment, and what spin diffusion there is can usually readily be identified from the relative sign of the corresponding cross peaks.

Against these advantages, there are some difficulties that arise from the application of the spin locking field. Significant resonance offset effects are inevitable at the relatively low spin locking field strengths that can be applied in practice, implying that the cross relaxation controlling cross-peak intensities will, in general, be a composite of longitudinal and transverse contributions. Also, for coupled spins that are symmetrically disposed about the spin lock frequency, or are both close to it, a net transfer of magnetization may occur through the scalar coupling via the homonuclear Hartmann–Hahn (HOHAHA) interaction. Multistep mechanisms involving both HOHAHA transfer and ROE transfer may also occur, making the interpretation of ROESY data potentially quite complicated (see also **TOCSY in ROESY and ROESY in TOCSY**).²⁹

Nonetheless, there have been many applications of the ROE in the decade or so since its discovery. Mainly, these have been to intermediate-sized molecules, such as small peptides, that often give very poor NOESY spectra. However, it may also be worthwhile running a series of conventional steady state NOE difference spectra, since these are often significantly more sensitive than NOESY for such systems. For macromolecules, although clearly ROESY does not supplant NOESY for obtaining internuclear distance constraints, it can be very useful to compare NOESY and ROESY data in order to help identify spin diffusion pathways in the former.

7 THE HETERONUCLEAR NOE

Figure 9 shows the maximum theoretical steady-state heteronuclear two-spin NOE enhancement ($\eta_{\max}$) for the

Figure 9 Maximum theoretical two-spin NOE enhancements ($\eta_{\max}$) for various heteronuclear systems relaxing exclusively via dipolar interaction, as a function of $\omega\tau_c$. Note that for ^{15}N , the NOE can be negative, and that for ^{13}C and ^{31}P the NOE becomes very small for large molecules

more important heteronuclei and hydrogen, calculated using equations (4)–(6). The commonest application of these heteronuclear NOE enhancements is for sensitivity improvement during direct observation of heteronuclear signals, e.g. the application of ^1H decoupling when acquiring ^{13}C spectra of small molecules (at the extreme narrowing limit, $\eta_{\max}$ for the $^{13}\text{C}\{^1\text{H}\}$ NOE is 199%, corresponding to a threefold gain in signal). Note that $\eta_{\max}$ also corresponds to the theoretical NOE ($\rho^* = 0$) seen in a multispin system when all spins but one are saturated (provided all the saturated spins have the same γ).⁵ However, any value of $\eta_{\max}$ between 0% and –200% means that saturation of the protons causes a *reduced* intensity for the X resonances, and a value of –100% means they are destroyed altogether. Inspection of the curves in Figure 9 shows that such circumstances do occur in some cases where γ_X is negative, e.g. for $^{15}\text{N}\{^1\text{H}\}$ with $\omega_N\tau_c \approx 0.5$. In such cases, if proton decoupling is to be used to collapse the X resonance multiplet structures, it should be applied in a gated fashion during the acquisition time only, and be switched off during the relaxation delay. In several other cases, the heteronuclear NOE becomes very small for slowly tumbling molecules, e.g. at the spin diffusion limit $\eta_{\max}$ for the $^{13}\text{C}\{^1\text{H}\}$ NOE is 15.4%, and for the $^{31}\text{P}\{^1\text{H}\}$ NOE it is only 2.2%. For these cases, there is of course virtually no sensitivity gain to be had from the heteronuclear NOE.

Measurements of specific heteronuclear enhancements to aid in structure determination are much less common than homonuclear applications because the sensitivity of the experiments is much lower, but several applications to small molecules have appeared.³⁰ Although the NOE observed on protons is a lot smaller than that observed on the X resonance, it is still often preferable to use proton observation as the sensitivity gain from detecting the higher frequency nucleus more than compensates; however, such ^1H -detected (inverse) NOE experiments may be compromised by inferior subtraction quality if the X nucleus is a dilute spin. Another factor that makes heteronuclear NOE experiments difficult is that the buildup rate σ_{XH} is slower than the corresponding interproton rate by a factor of $(\gamma_{\text{H}}/\gamma_X)^2$, for the same internuclear

separation. Thus specific steady-state heteronuclear NOE difference experiments with small molecules can be extremely time-consuming, while experiments with macromolecules are usually precluded by the small values of $\eta_{\max}$. Even in cases where $\eta_{\max}$ appears to behave quite similarly to that for the interproton NOE (e.g. for $^{19}\text{F}\{^1\text{H}\}$), one must remember that in the spin diffusion limit W_0 transitions will always be more efficient for the homonuclear case, since for sufficiently large molecules the tumbling rate will always be slower than the heteronuclear frequency difference ($\omega_I - \omega_S$). Thus, for example, in a $^1\text{H}\{^{19}\text{F}\}$ NOE experiment where a single fluorine resonance is saturated in a macromolecule, the buildup of heteronuclear enhancements at the nearest protons will be much slower than the dissipation of those enhancements onto other protons via homonuclear spin diffusion.

Recently, one of the more significant uses for heteronuclear NOE measurements (in conjunction with X nucleus T_1 and T_2 values) has been in the determination of local flexibility in macromolecules (see *Protein Dynamics from NMR Relaxation*). Typically, for each ^{15}N resonance in a ^{15}N -labeled protein, the corresponding T_1 , T_2 , and $^{15}\text{N}\{^1\text{H}\}$ steady-state NOE would be measured, and these data analyzed using a suitable formalism, most commonly the ‘model-free’ formalism of Lipari and Szabo.³¹ For internal motions of the ^{15}N – ^1H vector that are faster than the overall molecular tumbling, this approach yields an ‘order parameter’ S^2 that describes the geometric extent of the internal motion relative to the molecular frame; $S^2 = 1$ implies complete rigidity, while $S^2 = 0$ implies the internal motion is isotropic relative to the molecular frame.

8 EXCHANGING SYSTEMS AND THE TRANSFERRED NOE

There are many types of exchange that can affect NMR spectra, including chemical exchange of labile protons (OH, NH, etc.) in protic solvents, conformational equilibria, and exchange of a solute between free and bound states. The effects that these processes have on NOE experiments depends mainly on their rate, relative both to the T_1 timescale and to the chemical shift timescale (see also *Relaxation Effects of Chemical Exchange*). If exchange is slow relative to T_1 , then NOE enhancements will evolve largely unaffected by the exchange process. However, if exchange is fast relative to T_1 , then many exchange events will occur during NOE evolution, causing the various relaxation rates themselves to be averaged, and it will be as though the NOE had evolved in an ‘averaged molecule’. Thus, if two resonances are linked by exchange that is faster than T_1 , irradiation of one will result in saturation of both (saturation transfer), and if one resonance receives an NOE enhancement, exchange will transfer the enhancement onto the second resonance also. Under these circumstances, NOE enhancements will reflect so-called ‘ $\langle r^{-6} \rangle$ average’ distances, defined as

$$\langle r_{IS}^{-6} \rangle = \left[\frac{1}{N} [(r_{IS}^A)^{-6} + (r_{IS}^B)^{-6} + \dots + (r_{IS}^N)^{-6}] \right]^{-1/6} \quad (22)$$

where r_{IS}^A, r_{IS}^B , etc. represent the IS internuclear distance in each of the N exchanging forms of the system. For internal

motions faster than overall molecular tumbling, it transpires that $\langle r^{-3} \rangle$ averaging of distances is appropriate, and that in addition there is a geometry-dependent reduction of NOE enhancements caused by the anisotropy of the internal motion with respect to the molecular frame; this situation usually applies for methyl group rotations.³²

Note that the rate of exchange relative to $\Delta\delta$ (the chemical shift difference for the same spin in its two environments, for the case of two-site exchange) does not directly affect the NOE intensities at all; however, it does affect the number of separate resonances in the spectrum, and thereby dictates what NOE interactions can be measured separately. In cases of exchange which is slow relative to $\Delta\delta$, where separate signals are seen for each exchanging species, exchange can provide an additional mechanism for magnetization transfer in NOE experiments. For large molecules in conventional NOE experiments, exchange that is fast on the T_1 timescale causes saturation transfer signals that have the same sign as the NOE-enhanced signals; a distinction between the two types of signal can generally only be made on grounds of intensity or buildup rate. Conversely, for conventional NOE experiments with small molecules, and for ROE experiments with any size of solute, exchange will lead to signals of opposite sign to direct enhancements. Although this implies that they have the same sign as indirect enhancements transmitted over one intermediate spin, in the context of a general interpretation of all the cross peaks, the distinction between these two types of signal is usually quite straightforward.

More insidious than the signals due to exchange itself, however, is the possibility that conformational averaging affects the NOE intensities, giving results that reflect an 'averaged structure'. This can lead to data that are inconsistent with any single structure. In the case of slow exchange on the chemical shift timescale there is likely to be warning of the danger since multiple resonances are observed, but in the case of fast exchange on the chemical shift timescale there may be no indication of conformational exchange other than mutual inconsistencies amongst the NOE intensities. If models of the separate exchanging conformers are available from some other source, then in principle it is possible to fit the NOE data, using the relative proportions of the conformers as one of the fitting variables; however, this process is difficult and, given the r^{-6} dependence of the NOE, very heavily dependent upon the accuracy of the initial models. In large molecules, the main issue concerning conformational exchange is usually how to allow for relatively small-scale local motions when interpreting NOE data. These have two principal effects: they reduce the size of the enhancements, by making the effective τ_c shorter, and they change relative intensities by altering the values of $\langle r^{-6} \rangle$. For small-scale motions, these effects are both taken into account, at least approximately, by specifying NOE-derived distance constraints as ranges rather than specific distances, as mentioned earlier.

A particularly significant case of the influence of exchange is in the transferred NOE, or TRNOE experiment. Suppose a small ligand binds to a large molecule, and that exchange between the free and bound states is fast both on the T_1 and chemical shift timescales. The ligand resonances and also its intramolecular NOE enhancements will be averaged over the free and bound states by such an exchange. If the ligand is present in moderate excess, then the averaged ligand resonances will largely retain the narrow linewidths

associated with the free ligand. However, because the tumbling rate of the ligand when bound to the large molecule is very much slower than in the free state, dipolar relaxation rates will be very much faster for the bound ligand than for the free [equations (4)–(6)]. Therefore, the observed NOE interactions will be dominated by the bound state, and thus reflect the bound conformation of the ligand, even though the free ligand concentration is higher than the bound. Although the first applications involved one-dimensional experiments, TRNOE experiments are now usually carried out using either NOESY or ROESY. Typical applications include studies of inhibitors bound to enzymes and small peptides bound to immunoglobulins; however, the generality of the technique is somewhat limited by the requirements for suitable exchange rates for the ligand–macromolecule interaction.³³ More recently, related experiments have been used to investigate protein hydration using intermolecular NOE enhancements between the protein surface and water protons (see *Protein Hydration*).

1 INTRODUCTION

Paramagnetic systems are materials with positive magnetic susceptibility, normally associated with unpaired electrons. Chemically, paramagnetic systems of relevance for this article are dilute aqueous or organic solutions of free radicals and transition metal ions or their complexes, including metalloproteins. The presence of unpaired electron spins has a profound influence on the NMR spectra of such solutions. The origin of the effects is to be found in the large value of the electronic magnetic moment, about 650 times that of the proton.

The influence of the paramagnetic species on NMR spectra of liquids may be two-fold. First, the nuclear spin relaxation rates are enhanced. The paramagnetic relaxation enhancement (PRE) is caused by random variation of the electron spin–nuclear spin interactions, which opens new pathways for longitudinal as well as transverse relaxation. The PRE is most often studied for $I = \frac{1}{2}$ nuclei, but oxygen-17 applications are not uncommon. Second, the NMR signals may be shifted, provided the relevant electron spin–nuclear spin interaction has a nonzero average. Paramagnetic complexes in solution often contain exchangeable ligands, and the exchange phenomena (see *Chemical Exchange Effects in Biological Macromolecules*), together with the intrinsic relaxation rates and shifts, contribute to the observed lineshapes and line positions. The paramagnetic effects have been used for several decades by chemists and biochemists as a source of structural, thermodynamic, and dynamic information. Applications of this type have been described in numerous books, recently by Bertini and Luchinat¹ and by Banci et al.² A more recent application of PRE is the use of paramagnetic compounds as contrast agents in MRI (see *Contrast Agents in Whole Body Magnetic Resonance: An Overview* and *Contrast Agents in Magnetic Resonance: Operating Mechanisms*).

2 THEORY

The theory of nuclear relaxation in paramagnetic systems contains many intricate points, described some years ago in a review article.³ Here, we concentrate on the most important issues and begin by formulating the relationships between the

measured macroscopic PRE and the microscopic quantities. We then proceed with the theory for relaxation times for nuclei residing in the ligands in paramagnetic complexes and conclude the theory section by a brief discussion of intermolecular relaxation.

2.1 The Macroscopic and Microscopic Quantities

The PRE experiments are often performed with a considerable excess of a ligand (e.g. solvent) over the paramagnetic centers (e.g. transition metal ions). The type of information obtainable from PRE measurements in solution depends on the relative magnitudes of the exchange rates, the intrinsic relaxation rates, and shifts. The set of equations relating the relaxation, shift, and lifetime properties of the nuclei in paramagnetic complexes to the observables of the NMR experiments has been derived by Swift and Connick⁴ and by Luz and Meiboom.⁵

$$T_{1P}^{-1} = \frac{P_M}{\tau_M + T_{1M}} \quad (1)$$

$$T_{2P}^{-1} = \frac{P_M}{\tau_M} \left[\frac{T_{2M}^{-2} + (T_{2M}\tau_M)^{-1} + \Delta\omega_M^2}{(T_{2M}^{-1} + \tau_M^{-1})^2 + \Delta\omega_M^2} \right] \quad (2)$$

$$\Delta\omega_P = \frac{P_M\Delta\omega_M}{(\tau_M/T_{2M} + 1)^2 + \tau_M^2\Delta\omega_M^2} \quad (3)$$

T_{1P}^{-1} , T_{2P}^{-1} , and $\Delta\omega_P$ are the excess (see Section 3) spin–lattice relaxation rate, spin–spin relaxation rate and shift measured for the ligand in solution, while the properties with index M refer to the ligand in the paramagnetic complex. τ_M is the lifetime of the ligand in the complex and P_M is the mole fraction of ligand nuclei in bound positions.

2.2 The Modified Solomon–Bloembergen Equations

The nuclear spin relaxation in a paramagnetic complex arises through the electron–nucleus hyperfine interaction (see *Electron-Nuclear Interactions*) between the nuclear spin I and the electron spin S . The hyperfine interaction consists of two parts. The first term is the dipole–dipole interaction between the nuclear magnetic moment and the electron spin of the electron outside of the nucleus; the second term is the scalar interaction or Fermi contact coupling between the nuclear magnetic moment and the spin of s electrons at the site of the nucleus. Each of these terms can be modulated by random processes and can contribute to the nuclear relaxation rates. The dipole–dipole part of the hyperfine interaction is modulated by reorientation of the spin–spin axis, by changes in the orientation of the electron spin (electron spin relaxation) and by ligand exchange. The scalar interaction part remains unaffected by reorientation of the molecule and is only modulated by electron relaxation and ligand exchange.

These qualitative ideas are reflected in the set of equations for nuclear relaxation rates in paramagnetic complexes, known as the ‘modified Solomon–Bloembergen equations’:

$$\begin{aligned}
T_{1M}^{-1} &= (T_{1M}^{SC})^{-1} + (T_{1M}^{DD})^{-1} \\
&= \frac{2}{3} \left(\frac{A}{\hbar} \right)^2 S(S+1) \frac{\tau_{e2}}{1 + (\omega_S - \omega_I)^2 \tau_{e2}^2} \\
&\quad + \frac{2}{15} \left(\frac{\mu_0}{4\pi} \right)^2 S(S+1) \hbar^2 \gamma_I^2 \gamma_S^2 R^{-6} \\
&\quad \times \left[\frac{\tau_{c2}}{1 + (\omega_S - \omega_I)^2 \tau_{c2}^2} + \frac{3\tau_{c1}}{1 + \omega_I^2 \tau_{c1}^2} \right. \\
&\quad \left. + \frac{6\tau_{c2}}{1 + (\omega_S + \omega_I)^2 \tau_{c2}^2} \right] \quad (4)
\end{aligned}$$

and

$$\begin{aligned}
T_{2M}^{-1} &= (T_{2M}^{SC})^{-1} + (T_{2M}^{DD})^{-1} = \frac{1}{3} \left(\frac{A}{\hbar} \right)^2 S(S+1) \\
&\quad \times \left(\tau_{e1} + \frac{\tau_{e2}}{1 + (\omega_S - \omega_I)^2 \tau_{e2}^2} \right) \\
&\quad + \frac{1}{15} \left(\frac{\mu_0}{4\pi} \right)^2 S(S+1) \hbar^2 \gamma_I^2 \gamma_S^2 R^{-6} \\
&\quad \times \left[4\tau_{c1} + \frac{3\tau_{c1}}{1 + \omega_I^2 \tau_{c1}^2} + \frac{\tau_{c2}}{1 + (\omega_S - \omega_I)^2 \tau_{c2}^2} \right. \\
&\quad \left. + \frac{6\tau_{c2}}{1 + \omega_S^2 \tau_{c2}^2} + \frac{6\tau_{c2}}{1 + (\omega_S + \omega_I)^2 \tau_{c2}^2} \right] \quad (5)
\end{aligned}$$

where

$$\tau_{ei}^{-1} = \tau_R^{-1} + \tau_M^{-1} + T_{ie}^{-1} \quad (i = 1, 2) \quad (6)$$

$$\tau_{ei}^{-1} = \tau_M^{-1} + T_{ie}^{-1} \quad (7)$$

τ_R is an isotropic rotational correlation time of the complex, T_{ie} ($i = 1$ or 2) is the electron spin relaxation time, and S is the electron spin quantum number, $A/\hbar$ is the isotropic scalar coupling constant, μ_0 is the permeability of vacuum, R is the distance between the nuclear spin and the electron spin (considered as a point dipole), and γ_S equals $g_{\text{eff}}\beta/\hbar$, where g_{eff} is the effective g factor of the electron in the complex under consideration and β is the Bohr magneton. ω_S and ω_I are the electronic and nuclear Larmor frequencies. The electronic Larmor frequency is so much larger than the nuclear Larmor frequency that the latter can be neglected in the terms involving the sum and difference frequencies, and some of the terms in the dipole–dipole parts of equations (4) and (5) can be brought together. Note the peculiar dual role that the exchange can play in the PRE: in equations (4)–(7) the τ_M acts as a correlation time, while its role in equations (1)–(3) is that of a relaxation time.

The modified Solomon–Bloembergen equations were first presented in the papers by Connick and Fiat⁶ and by Reuben et al.⁷ The formal derivation of the equations is fairly complicated and was in fact published much later.⁸ It is based on the Redfield relaxation theory for the nuclear spin and involves two critical assumptions. The first one is that the

electron relaxation (which is a motion in the electron spin space) is uncorrelated with molecular reorientation (which is a spatial motion influencing the dipole coupling). The second assumption is concerned with the description of the dynamics in the electron spin space. It is assumed that the electron spin system is dominated by the electronic Zeeman interaction. Other interactions lead to relaxation, which can be described in terms of the longitudinal and transverse relaxation times T_{1e} and T_{2e} . This point is elaborated on in Section 2.3. In this sense, one can call the modified Solomon–Bloembergen equations a ‘Zeeman-limit theory’. If the second assumption is fulfilled, then the scalar interaction parts in equations (4) and (5) become analogous to the equations describing scalar relaxation originating from the modulation of the nuclear spin–spin coupling, with the hyperfine coupling constant $A/\hbar$ replacing the J coupling constant. The first assumption does not directly influence the scalar interaction term, but the failure to fulfil it will lead to an additional interference (cross correlation) term between the dipole–dipole and the scalar interactions. The validity of both the above assumptions is questionable in many cases of practical importance.

Apart from these two main assumptions, equations (4) and (5) contain several additional approximations, the most important of which are the following:

1. The electron spin is assumed to be a point dipole centered at the metal ion. The validity of this assumption can be tested by ab initio quantum-chemical calculations, which indicate that it is reasonable for protons but may cause errors for heavier nuclei, in particular if the atoms where they reside are involved in bonding with the paramagnetic metal center.⁹
2. The electron g tensor is assumed to be isotropic. The effects of deviations from this assumption were first investigated by Sternlicht.¹⁰
3. It is assumed that the reorientation of the nuclear–electron spin vector can be described by a single correlation time, τ_R . This amounts to neglecting the effects of internal motion and anisotropic reorientation.
4. It is assumed that chemical exchange is uncorrelated with the remaining motions in the lattice. This assumption seems to be easy to fulfil. We return to the exchange effects in Section 3.1.

2.3 The Bloembergen–Morgan Theory for Electron Spin Relaxation

As one can see in equations (4) and (5), the magnitude of the PRE for the ligand nuclei depends on the energy level splittings and the relaxation behavior of the electron spin system of the transition metal ion in the magnetic field. For discussing the splittings, the spin Hamiltonian formalism, developed originally for the interpretation of ESR spectra,¹¹ normally constitutes an appropriate framework. The spin Hamiltonian is an operator involving only nuclear and electron spin operators and parameters characterizing the spin system under consideration. Neglecting the terms containing only nuclear spins and the hyperfine coupling to the ligand nuclei, the spin Hamiltonian can be written:

$$\hat{H}_S = \hat{S} \cdot \mathbf{g} \cdot \hat{B}_0 + \hat{S} \cdot \mathbf{D} \cdot \hat{S} + \hat{S} \cdot \mathbf{A} \cdot \hat{I}_M \quad (8)$$

$\hat{S}$ is the electron spin operator. The first term describes the electron Zeeman interaction and the second the zero-field splitting (ZFS) interaction, which only has to be considered for systems with electron spin quantum number $S \geq 1$. The last term corresponds to the hyperfine interaction with the metal nucleus, if it has nonzero spin ($\hat{I}_M$ is the nuclear spin operator for the metal). The molecular parameters are the three second-rank tensors: the g tensor $\mathbf{g}$, the ZFS tensor $\mathbf{D}$ and the hyperfine coupling tensor $\mathbf{A}$. The combined effect of the electrostatic interactions and spin-orbit coupling renders the Zeeman interaction anisotropic and makes the average effective g value (equal to one-third of the trace of the g tensor) different from the free electron value of 2.0023. The effect of the g tensor on ESR spectra is similar to the effect of the shielding tensor in NMR.

The zero-field splitting tensor also has its origin in the intermingling of the electrostatic and spin-orbit interactions. In addition, the dipolar coupling between the electron spins can contribute to the ZFS, but this contribution is believed to be minor for transition metal complexes.¹² The ZFS tensor is traceless and can be characterized, in its principal axis system, by two constants:

$$D = D_{zz} - \frac{1}{2}(D_{xx} + D_{yy}) \quad (9a)$$

$$E = \frac{1}{2}(D_{xx} - D_{yy}) \quad (9b)$$

The ZFS interaction has a form similar to the quadrupolar interaction in NMR.

The modulation of various terms in equation (8) by random processes in liquids leads to electron spin relaxation. The rotational modulation of the anisotropies of the g and hyperfine tensors are important sources of electron relaxation for $S = \frac{1}{2}$ systems. Still another relaxation mechanism for $S = \frac{1}{2}$ systems, in analogy with the case of nuclear relaxation, is the spin-rotation coupling. The electron relaxation in $S = \frac{1}{2}$ systems is discussed at length in the book by Muus and Atkins¹³ and is summarized in the book by Banci et al.²

For systems with $S \geq 1$, the electron spin relaxation is usually so fast (often on the picosecond timescale) that it competes effectively with complex reorientation as the main modulation mechanism for the dipole-dipole part of the modified Solomon-Bloembergen equations, even in small complexes. Bloembergen and Morgan¹⁴ presented, as early as the early 1960s, a Redfield-type theory (see *Relaxation Theory: Density Matrix Formulation*) where they related this efficient electronic relaxation in hexaaquo complexes of transition metal ions to the modulation of the ZFS by the distortion of the hydration shell. The Bloembergen-Morgan equations for T_{1e} and T_{2e} are often written as

$$T_{1e}^{-1} = \frac{\Delta^2}{25} [4S(S+1) - 3] \left(\frac{\tau_v}{1 + \tau_v^2 \omega_S^2} + \frac{4\tau_v}{1 + 4\tau_v^2 \omega_S^2} \right) \quad (10)$$

$$T_{2e}^{-1} = \frac{\Delta^2}{50} [4S(S+1) - 3] \times \left(3\tau_v + \frac{5\tau_v}{1 + \tau_v^2 \omega_S^2} + \frac{2\tau_v}{1 + 4\tau_v^2 \omega_S^2} \right) \quad (11)$$

where τ_v is the correlation time for the collision-related modulation of the ZFS, and Δ^2 is the trace of the square of the transient ZFS tensor:

$$\Delta^2 = D_{xx}^2 + D_{yy}^2 + D_{zz}^2 = \frac{2}{3}D^2 + 2E^2 \quad (12)$$

The combination of the modified Solomon-Bloembergen equations with the Bloembergen and Morgan theory for electron spin relaxation rates provides a complete theory for the magnetic field dependence of the PRE, known in the literature as the Solomon-Bloembergen-Morgan (SBM) theory.

The Bloembergen-Morgan theory has rather severe validity conditions, very clearly stated in the original paper. The most important limitation is the validity requirement for the Redfield-type or perturbative approach, which can generally be formulated as $\tau_v^2 \Delta^2 \ll 1$. It is unfortunately rather common in the literature to use equations (10) and (11) uncritically, also beyond the limits of their validity. Analogous equations have also been derived for the case of rotational modulation of a static ZFS.¹⁵ This case should be handled with care in the context of PRE, because it violates the requirement of no correlation between rotation and electron relaxation. An improvement of the SBM theory, within the same general framework and with the same validity limits, has been proposed by Rubinstein et al.¹⁶ They noted that for systems with $S \geq \frac{3}{2}$ one may have more than one electronic T_1 or T_2 , and they elegantly described the collision modulation of the ZFS as a pseudorotation process.

The issue of the electron spin relaxation for $S \geq 1$ in solution is not really settled, on the fundamental level of the applicability of the spin Hamiltonian formalism. An interesting line of thought, which still awaits a quantitative formulation, is that the electronic relaxation in liquids might in fact be similar to that in solids, where one talks about mechanisms involving interactions between the electron spin and phonons, mediated by the spin-orbit coupling.²

2.4 Beyond the Solomon-Bloembergen-Morgan Theory

During the last decade, significant effort has been invested into moving the paramagnetic relaxation theory beyond the limitations of the SBM theory. Two main approaches can be discerned. One of them can be referred to as 'low-field theories'. These are designed to handle cases when the electron Zeeman interaction does not dominate the energy level structure, either because the slow reorientation does not average out the anisotropic term in equation (8) or because another interaction (in the first place the ZFS interaction) simply is stronger and determines the quantization direction of the electron spin. This approach was originally proposed by Lindner¹⁷ and was subsequently developed by Bertini and co-workers^{1,2} and by Sharp.¹⁸ The form of the resulting equation for T_{1M}^{-1} is similar to equation (4), in the sense that it consists of a sum of terms containing spectral density functions at the transition frequencies in the combined nuclear spin-electron spin system. The coefficients of the various spectral densities depend on the angle between the two molecule-fixed axis systems: the dipole-dipole axis and the principal axis of the anisotropic interaction. The electron spin relaxation enters the theories of this type in the simple form of 'electron relaxation

time', $\tau_S = T_{1e} = T_{2e}$, i.e. the electron spin is assumed to be in the Redfield limit. In addition, a frequency dependence of τ_S , similar to that given by the Bloembergen–Morgan theory, is sometimes used.

The other approach tries to solve the problem using more general, and more cumbersome, methods^{3,8,19,20} based on the stochastic Liouville equation (see *Liouville Equation of Motion*).¹³ This formulation is often referred to as the 'slow-motion approach'. The nuclear spin is considered to be weakly coupled (in the sense that the Redfield formalism is valid) to a composite lattice, containing the electron spin degree of freedom as well as rotations and possibly other classical degrees of freedom. The electron spin and the classical degrees of freedom are coupled through the ZFS interaction of arbitrary strength. The dynamics in the composite lattice can be described in terms of a spectral density function, and the nuclear T_1 is determined by the value of the spectral density at the nuclear Larmor frequency, while the nuclear T_2 depends on the spectral density at the nuclear Larmor frequency and at zero frequency. There is no need to invoke the concept of electronic relaxation time, even though the result of numerical calculations becomes identical to the SBM theory under appropriate limiting conditions. The disadvantage of the approach is its complexity: the composite lattice spectral density is obtained by the inversion of a complex matrix, in principle of infinite dimensions.

The magnetic field dependences of the nuclear spin–lattice relaxation rate, calculated using the methods of Bertini et al.² and of Benetis et al.,⁸ have been compared with each other, imposing on the latter model the additional assumption of exponential electron spin relaxation.² For the case of large ZFS, the results of the two methods are identical and very different from the predictions of the SBM theory (Figure 1).

Figure 1 Calculated magnetic field dependence of proton T_{1M}^{-1} in an $S = 1$ system according to the modified Solomon–Bloembergen equations (---), a low-field theory (—), and the slow-motion approach (o). 2.5 The Curie Spin Relaxation

Gueron, Fiat, and Vega²¹ have proposed an additional mechanism for the PRE, due to dipolar coupling of the nuclear spin with the thermally averaged electron magnetic moment. This average 'Curie spin' is aligned along the external magnetic field and is proportional to its magnitude. The interaction between the nuclear spin and the Curie spin is modulated by reorientation and exchange, but not by the electron spin relaxation. If the electron relaxation is much faster than the reorientation and exchange, and if the magnetic field is high, the Curie spin relaxation can become important (in particular for T_{2M}) in spite of the fact that the average electronic magnetic moment is of course much smaller than the real, rapidly oscillating one.

2.6 Intermolecular Relaxation

The above-mentioned theories of intramolecular nuclear spin relaxation due to dipole–dipole interaction assume that the distance R between the I and S spins is constant. The chemical exchange can be thought of as an extremely crude way of incorporating possible intermolecular effects or modulation of the dipole–dipole interaction by the variation of the interspin distance; it is allowed to be given a value of either R or infinity. For many transition metal complexes, this essentially intramolecular approach is sufficient. For other systems, where the paramagnetic centers in solution are either transition metal complexes with a nonlabile coordination sphere, or stable organic radicals, the relaxation of the solvent nuclei is predominantly intermolecular in nature (the concept of outer sphere relaxation is also used), and a more refined approach to the modulation of the spin–spin distance by translational diffusion is required. The problem can be solved at different levels of sophistication. The earlier development has been reviewed by Kowalewski et al.³ Among more recent contributions, one should mention the work of Bayburt and Sharp²² dealing with the limiting case of ZFS dominating over the electron Zeeman interaction.

3 EXPERIMENTAL METHODS

Most experimental work on PRE is technically very simple. Basically, one measures the nuclear spin–lattice or spin–spin relaxation rate (the latter is commonly estimated from the linewidth) for ligand nuclei in the presence and in the absence of the paramagnetic reagent, and one obtains the PRE by subtraction. The experiments are often performed to yield the result as a function of concentration of the paramagnetic species, temperature, pressure, or magnetic field. Variable concentration work can provide information on complexation equilibria. Variable temperature measurements can be used to clarify the relationships between the relaxation and exchange processes. Variable pressure experiments provide mechanistic information on the exchange processes (see *Kinetics at High Pressure*). Variable field measurements are PRE experiments *par excellence*, if one is interested in verifying theoretical models. The variable temperature and variable field measurements are discussed in the following two sections, and the experimental section is concluded by a brief presentation of

the paramagnetic relaxation effects in certain two-dimensional experiments.

3.1 Variable Temperature: Fast and Slow Exchange

As can be seen from equations (1)–(3), the relationship between relaxation and exchange is simplest for the spin–lattice relaxation, where one can easily define two limiting conditions: fast exchange, $\tau_M \ll T_{1M}$; and slow exchange, $\tau_M \gg T_{1M}$. Assume a simple case of a small complex in low viscosity solution, with T_{1M} dominated by the dipole–dipole interaction and with the reorientation of the complex determining τ_{c1} and τ_{c2} . For such a case, we are likely to have $(\tau_{c1} \omega_I)^2 \ll 1$ and $[\tau_{c2} (\omega_S \pm \omega_I)]^2 \ll 1$ and, as the rate of reorientation increases with increasing temperature, the nuclear relaxation rate decreases. The opposite is true for the ligand exchange—the rate is going to increase with increasing temperature. The measurements of the PRE in the slow exchange regime give directly the exchange lifetime and its temperature dependence/activation parameters. Measurements in the fast exchange limit provide the relaxation rate in the paramagnetic complex which, given a suitable theoretical model, can yield information on structural as well as dynamic parameters. The slow and fast exchange conditions can also be formulated for paramagnetic line broadening, a quantity commonly measured in variable temperature studies. An example of variable temperature ^{17}O line-broadening data, taken from the work of Hugi et al.,²³ is shown in Figure 2.

3.2 Variable Field: Physics of Relaxation

When one wishes to reach a deeper understanding of the details of the relaxation mechanism, a variable field [nuclear magnetic relaxation dispersion (NMRD)] study is a very powerful tool. Changing the magnetic field provides a direct

Figure 2 Oxygen-17 T_{2r}^{-1} in aqueous solution of a Ti(III) salt as a function of reciprocal temperature. Measurements were made at: (Δ , $\blacktriangle$) 8.4 T, ($\square$, $\blacksquare$) 4.7 T, and ($\circ$, $\bullet$) 1.4 T. Open and filled symbols refer to different pH values. way of measuring the frequency dependence of the relevant spectral densities.

Figure 2 gives an example of a variable field T_2 study. More commonly, the variable field studies are concentrated on T_1 measurements. Besides performing the regular inversion–recovery experiments at as many high-field spectrometers as possible, it is useful to apply field cycling experiments (see **Field Cycling Experiments**) to obtain the PRE also at very low magnetic fields. An illustrative example of the use of NMRD over a very wide range of magnetic fields is provided by the water proton relaxation in an aqueous solution of Mn(II) ions. The first field cycling experiments for this system were reported as early as the 1960s.²⁴ More recent data, as a function of solution viscosity varied by means of adding glycerol, are shown in Figure 3, taken from Bertini et al.²⁵ The Mn(II) ion is characterized by very small ZFS and slow electron spin relaxation; the data in Figure 3 can be interpreted successfully using the SBM theory. The scalar relaxation is observed at low field, because the electron relaxation is slow. In pure water, the scalar contribution disperses at ω_I of about 0.1 MHz, where $(T_{2e}\omega_S)^2$ becomes larger than unity. At higher fields, the dipolar relaxation dominates, and the second dispersion at ω_I of about 10 MHz corresponds to the condition $\omega_S\tau_R = 1$. Upon increasing the glycerol content, the viscosity increases, and both τ_R and τ_v increase with it, which changes the NMRD profiles.

A different case is presented by the PRE of water protons in an aqueous solution of another divalent first-row transition metal ion, Ni(II). An NMRD curve for this system, taken from work by Kowalewski et al.,²⁶ is shown in Figure 4. Here, the field dependence of the PRE is much weaker. The origin of this different behavior is to be sought in the electron relaxation in Ni(II), much faster than in the case of Mn(II). In fact, the nuclear and electron relaxation in aqueous Ni(II) is beyond the validity region of the SBM theory, and the details of the analysis of the data in Figure 4 are still not

Figure 3 Water ^1H NMRD profiles of Mn(II) solutions in pure water ($\circ$) and with increasing amounts of deuterated glycerol [($\bullet$) 10%, (∇) 20%, ($\blacktriangledown$) 35%, ($\square$) 55%, ($\blacksquare$) 65%]. completely settled.^{18,20,26} The flatness of the NMRD curve is caused by the rapid electron relaxation, which makes the scalar contribution negligible and reduces the efficiency of the dipole–dipole contribution. The weak increase of PRE at high field can be related to the onset of the dispersion of the electron relaxation.

The NMRD measurements are by no means limited to low-molecular-weight paramagnetic systems. A large number of data for metalloproteins in solutions can be found in the book by Banci et al.² and in a review by Koenig and Brown.²⁷

3.3 Novel Experiments

The last few decades have seen a tremendous growth in the number of available NMR experiments. In many of these experiments the paramagnetic relaxation effects are a nuisance, and are carefully avoided by removing oxygen and paramagnetic impurities from the samples. In some cases, however, paramagnetic systems can be studied, and special features introduced into common two-dimensional techniques (NOESY and COSY) by the paramagnetic relaxation are worth mentioning.

The NOESY experiment suffers from the PRE in the sense that the cross-relaxation rates involving nuclei close to paramagnetic centers become much smaller than the leakage rates, which reduces the intensity of the cross peaks. As demonstrated, by Emerson and La Mar²⁸ among others, it is nevertheless possible to perform NOESY studies of the active site regions of fairly large paramagnetic proteins. The COSY experiments suffer from the PRE because of rapid relaxation and excessive signal cancellation when the linewidth is much larger than the J coupling. COSY cross peaks have nevertheless been reported in paramagnetic proteins. The results may, however, require a reevaluation in the light of the recent work by Bertini et al.,²⁹ who have demonstrated that the cross peaks may actually arise through relaxation-allowed coherence transfer, originating from cross correlation of the dipole–dipole and Curie relaxation mechanisms, rather than through J couplings.

1 INTRODUCTION

Triple resonance (^1H , ^{13}C , ^{15}N) NMR techniques¹ have greatly reduced the effort required to obtain protein signal assignments as well as interproton distance and dihedral angle restraints.² This development has enhanced the prospects of obtaining information about protein structure. Such information is of widespread interest because it is fundamental for understanding protein function. However, proteins are not rigid bodies, but rather execute internal motions on a wide range of timescales.³ In order to understand important aspects of protein function such as folding, molecular recognition, and enzyme action, detailed knowledge about protein dynamics is essential. At a more fundamental physical level, experimental information about the amplitudes and rates of internal motions in proteins can be used to check the predictions of molecular dynamics trajectories. Such tests of theoretical calculations should result in improved formulas for the potential functions used in the computations.

Protein structures in solution are derived using restraints obtained almost exclusively from proton J couplings and NOEs,^{4,5} whereas information about the internal motions of proteins is derived most directly from measurements of spin relaxation rates of nuclei such as ^{15}N and ^{13}C (designated A spins herein).^{6–8} Although ^{13}C relaxation studies of proteins were initiated over a decade ago,⁸ these early studies were limited by the lack of sequential assignments as well as by the low resolution and sensitivity afforded by one-dimensional NMR spectra recorded with A spin detection. Fortunately, triple resonance experiments¹ provide sequential assignments of ^{15}N and ^{13}C nuclei along with those of protons. Hence, proton-detected two-dimensional heteronuclear relaxation experiments^{9–16} are a means of measuring A spin relaxation rates with high sensitivity and resolution.

2 THEORETICAL CONSIDERATIONS

2.1 Relaxation Equations

Elegant general formalisms relating nuclear spin relaxation to molecular motion have been provided by Abragam¹⁷ and Redfield.¹⁸ In the case of a spin $I = \frac{1}{2}$ A nucleus such as ^{13}C or ^{15}N directly bonded to N protons (designated X), the AX_N dipolar interactions and A-spin chemical shift anisotropy, CSA, are the significant relaxation mechanisms. Provided that cross correlations can be neglected, the A-spin longitudinal relaxation time, T_1 , transverse relaxation time, T_2 , and A- $\{\text{X}\}$ NOE, are given by^{9,17}

$$1/NT_1 = d^2[J(\omega_A - \omega_X) + 3J(\omega_A) + 6J(\omega_A + \omega_X)] + c^2J(\omega_A) \quad (1)$$

$$1/NT_2 = 0.5d^2[4J(0) + J(\omega_A - \omega_X) + 3J(\omega_A) + 6J(\omega_X) + 6J(\omega_A + \omega_X)] + \frac{1}{6}c^2[4J(0) + 3J(\omega_A)] \quad (2)$$

$$\text{NOE} = 1 + (\gamma_A/\gamma_X)d^2[6J(\omega_A + \omega_X) + J(\omega_A - \omega_X)]NT_1 \quad (3)$$

where ω_i is the Larmor frequency of spin i , $J(\omega)$ is the spectral density function, γ_i is the gyromagnetic ratio of spin i , $d^2 = 0.1[(\mu_0/4\pi)\gamma_A\gamma_Xh/(2\pi\langle 1/r_{\text{AX}}^3 \rangle)]^2$, $c^2 = \frac{2}{15}[\omega_A(\sigma_{\text{vert}} - \sigma_{\perp})]^2$, h is Planck's constant, r_{AX} is the AX bond length (0.102 nm for NH and 0.109 nm for CH), and $\sigma_{\parallel}$ and $\sigma_{\perp}$ are principal components of the axially symmetric CSA tensor. For the amide ^{15}N , the CSA is about 160 ppm,¹⁹ and at 11.7 T contributes nearly 20% to the ^{15}N relaxation rate. In contrast, the CSA contribution is much smaller in the case of aliphatic carbons. For example, the CSAs of rotating methyl and backbone α -carbons are about 25 and 35 ppm respectively, and, at 11.7 T, contribute less than 2.5% to ^{13}C spin relaxation.

As noted above, equations (1)–(3) are valid only when the effects of cross correlations are negligible. Although rf pulses can eliminate cross correlation of AX dipolar A-spin CSA interactions,¹¹ such pulses cannot completely eliminate the effects of dipolar cross correlations in AX_2 and AX_3 spin systems.²⁰ In general, A-spin magnetization relaxes in multiexponential fashion in AX_2 and AX_3 spin systems, and equations (1) and (2) yield the initial decay rates of longitudinal and transverse magnetization, respectively.²⁰

2.2 The Model-Free Formulation of the Spectral Density Function

In equations (1)–(3), the spectral density function contains the information about molecular motion. However, if experiments are recorded at a single external field, only three experimental parameters are measured, and hence the data are insufficient to determine the spectral density function at five frequencies. In principle, spectral densities at 11 frequencies can be determined from the set of 12 A-spin T_1 , T_2 , and NOEs measured at four magnetic fields: $\gamma_A\omega$, $\gamma_H\omega$, $(\gamma_H \pm \gamma_A)\omega$, where ω is the A-spin Larmor frequency at the lowest

field employed. However, the large value of γ_H/γ_A , requires that one data set be obtained at low field (<3.5 T) where sensitivity and resolution are poor. Spectral densities have been determined for eglin c from spectra recorded at a single high field by measuring an expanded set of relaxation parameters that include the relaxation of certain two-spin coherences and the selective proton longitudinal relaxation.¹⁶ A potential limitation of this approach is that the relaxation of the two-spin coherences contain a large contribution from the selective proton relaxation. This contribution must be subtracted from the two-spin relaxation in order to obtain reliable values of $J(\omega_i)$.

An alternative to direct determination of the spectral density functions is afforded by the model-free approach.^{6,7} According to this formalism, the spectral density function is expressed in terms of three motional parameters according to

$$J(\omega) = S^2 \tau_m / (1 + \omega^2 \tau_m^2) + (1 - S^2) \tau / (1 + \omega^2 \tau^2) \quad (4)$$

where S is the generalized order parameter, τ_m is the overall correlation time, and $1/\tau = 1/\tau_m + 1/\tau_e$, where τ_e is an effective correlation time characterizing the internal motions of the protein. Equation (4) is an exact expression provided that (a) the overall motion of the protein is isotropic and is not correlated with the internal motions, and (b) all correlation times associated with the internal motions are in the extreme narrowing limit. When internal motions take place on two significantly different timescales, a useful, approximate, generalization of equation (4) is

$$J(\omega) = S^2 \tau_m / (1 + \omega^2 \tau_m^2) + (1 - S^2) \tau_1 / (1 + \omega^2 \tau_1^2) + S_f^2 (1 - S_s^2) \tau_2 / (1 + \omega^2 \tau_2^2) \quad (5)$$

where S_f , τ_1 and S_s , τ_2 are order parameters and effective correlation times associated with the ‘fast’ and ‘slow’ (outside the extreme narrowing limit) internal motions, and $S = S_f S_s$.²¹

The analysis of relaxation data using the model-free approach yields the overall correlation time of the protein as well as values of S^2 and τ_e for individual amino acid residues in the protein. Because τ_e is, in general, a complex combination of geometric factors and internal correlation times it cannot be interpreted in a quantitative manner. However, its determination does provide an estimate of the timescale of the internal motion at a particular site in the protein. In contrast, the order parameter is precisely related to the amplitude of the internal motion.^{6,7} When the interaction responsible for relaxation is axially symmetric, with the symmetry axis along the AX bond, (rigorously true for the AX dipolar interaction and approximately so for the ¹⁵N amide CSA interaction) S^2 is given by

$$S^2 = \int d\Omega_1 p_{eq}(\Omega_1) \int d\Omega_2 p_{eq}(\Omega_2) P_2(\cos \theta_{12}) \quad (6)$$

where $p_{eq}(\Omega) d\Omega$ is the equilibrium probability that the unit vector along the AX bond axis has orientation $d\Omega$, $\Omega = (\theta, \phi)$, in a coordinate system fixed in the protein, θ_{12} is the angle between two such vectors, and $P_2(x) = (3x^2 - 1)/2$. The advantage of the model-free approach derives from the fact that values of S^2 are obtained for numerous sites in the protein without the need to assume an explicit model of the internal motion. Using equation (6) values of S^2 can be

calculated for any model of interest. Then, it can be determined if the model does indeed yield order parameters in agreement with experiment, and if the order parameters correspond to physically reasonable values of angular amplitudes of internal motion.

A useful and popular model of internal motion is diffusion in a cone, in which the AX bond axis is thought to diffuse freely in the angular region $0 \leq \theta \leq \theta_0$, $0 \leq \phi \leq 360^\circ$, where θ and ϕ are spherical, polar angles. For this model,

$$S^2 = [0.5 \cos \theta_0 (1 + \cos \theta_0)]^2 \quad (7)$$

so that the cone semiangle can be derived from the order parameter. Equation (7) reveals several general features about the relationship between the amplitude of angular reorientation and S^2 . S^2 equals unity when θ_0 is zero, diminishes as θ_0 increases, and vanishes when $\theta_0 = 180^\circ$, i.e., isotropic motion. Note however that S^2 is not a monotonic function of θ_0 , and vanishes when motion is not isotropic, $\theta_0 = 90^\circ$. In general, S^2 is large for a small amplitude motion, but the converse need not be true; for example, S^2 equals unity if the AX bond reorients by a two-site jump of 180° . Analytical expressions for S^2 are available for other plausible models of internal motion.^{6,7}

3 PULSE SEQUENCES AND DATA ANALYSIS

Two-dimensional heteronuclear pulse sequences designed to measure A-spin T_1 , T_2 , and NOE values in AX spin systems ($A = {}^{13}\text{C}$ or ¹⁵N, $X = {}^1\text{H}$) are depicted in Figure 1.^{9,14} In order to maximize sensitivity, A-spin magnetization is derived from proton magnetization using an INEPT scheme in the T_1 and T_2 pulse sequences, and proton detection is employed in all three experiments. The application of 180° proton pulses during the relaxation delay period, T , suppresses cross correlation of AX dipolar and A-spin CSA interactions. The NOE experiment is the least sensitive of the three measurements because one must record spectra starting with equilibrium A-spin magnetization (in the absence and presence of proton saturation), and it is necessary to wait a long period between scans ($\geq 3T_L$, where T_L is the larger of either the proton or the A-spin T_1 value) to ensure that the A-spin magnetization attains equilibrium. Also, when the spectrum is recorded in H₂O without a NOE, water saturation must be achieved quickly in order to minimize transfer of saturation from water to protein protons. Recently it has been shown that one can avoid water saturation in the NOE experiment using pulsed field gradients and water flip-back pulses.²²

Pulse sequences for measuring methyl ¹³C relaxation parameters, while similar to those depicted in Figure 1, differ from them in several significant respects.^{12,13,23} First, one must use magic angle delays in INEPT- or DEPT-type transfer steps in order to avoid complications that arise from dipolar cross correlations¹² and to ensure that carbon magnetization in $\frac{3}{2}$ and $\frac{1}{2}$ proton manifolds is faithfully transferred back to protons¹³ in the reverse INEPT or DEPT portions of the sequences. Second, a sequence of 125° proton pulses should be applied during the CPMG period in order to eliminate dipolar cross correlations from ¹³C transverse relaxation within the $\frac{3}{2}$ manifold. Third, the final delays, Δ , in the reverse INEPT portion of the sequence should be set to a short value, about

Figure 1 Pulse sequences used to measure A-spin (a) T_1 , (b) T_2 , and (c) A{-X} NOE in AX spin systems. The sequences are discussed in Kay et al.¹⁴

$1/[8J(C, H)]$, to minimize the effect of rapid proton relaxation upon the measurement of the ^{13}C relaxation rates. Finally, because the methyl ^{13}C NOE is large, there is no sensitivity loss in saturating the protons and initiating the T_1 and T_2 experiments with ^{13}C magnetization. Sequences for measuring methyl carbon relaxation have been discussed in detail,^{12,13,23} and Kay et al.¹³ have discussed the errors in T_2 measurements that are caused by (a) missetting the magic angle, and (b) rapid relaxation of proton magnetization in the $\frac{3}{2}$ manifold, when INEPT- and DEPT-type sequences are recorded without applying 125° pulses during the CPMG period. Application of 125° pulses, during the CPMG period, decreases (increases) the error in the T_2 measurement in the INEPT (DEPT)-type experiment caused by magic angle misset, and increases (decreases) error in the INEPT (DEPT) experiment caused by rapid proton relaxation.

Although the pulse schemes used to measure methyl relaxation minimize the effects of dipolar cross correlation, rf pulses cannot mix the $\frac{3}{2}$ and $\frac{1}{2}$ proton manifolds and therefore cannot completely eliminate such effects. Fortunately, dipolar cross correlations make very small contributions to T_1 and NOE of rapidly rotating methyl carbons in proteins in the 5–40 kDa molecular weight range.²⁴ Hence, equations (1) and (3) can be applied in the analysis of methyl carbon relaxation in proteins. However, the effects of dipolar cross correlations are significant in the case of transverse relaxation, and equation (2) provides the rate of the initial decay of

the methyl carbon transverse magnetization. Finally, we note that chemical exchange often contributes to T_2 relaxation in proteins. Because accurate T_2 values are obtained by the CPMG method only when $\delta \ll 1/[2J(A, X)]$,^{9,14,16} small δ values are employed in the CPMG sequence. For this reason, and because the maximum spin lock field that can be safely applied to protein solutions is about 10 kHz, chemical exchange often affects T_2 and $T_{1\rho}$ in a similar way. Therefore, even in the presence of chemical exchange, T_2 may be equal to $T_{1\rho}$. A significant increase in $1/T_2$, as the external field increases, is strong evidence that fast chemical exchange contributes to transverse relaxation.

In view of the large amount of data that is required to determine residue-specific relaxation parameters in proteins, surface fitting routines are an extremely useful means of determining signal positions and intensities in individual two-dimensional spectra. The derived signal intensities are fit to an equation of the form $y = A \exp(-t/T_i)$, $i = 1, 2$, using conjugate gradient minimization techniques,²⁵ and standard errors in A and T_i are obtained using a Monte Carlo approach.²⁶ The NOE values are determined by measuring the ratio of signal intensities in the presence and absence of proton saturation. The standard error in the NOE measurement is derived from the rms noise measured in a signal-free region of the spectrum.

Although the model-free approach can be applied when the overall motion of the protein is anisotropic,^{6,7,27} most globular

proteins have approximately spherical shapes, and it is usually assumed that the overall motion of the protein is characterized by a single overall correlation time, τ_m . In the framework of the model-free formalism, each NMR parameter is then related to three parameters: the global parameter τ_m , and two residue-specific internal motion parameters, S^2 and τ_e . A general approach to determine the three model-free parameters consists of minimizing the function^{25,28,29}

$$\chi^2 = \sum_i \{[(T_{1i}^{\text{obs}} - T_{1i}^{\text{cal}})/\sigma_{1i}]^2 + [(T_{2i}^{\text{obs}} - T_{2i}^{\text{cal}})/\sigma_{2i}]^2 + [(\text{NOE}_i^{\text{obs}} - \text{NOE}_i^{\text{cal}})/\sigma_{\text{NOE}_i}]^2\} \quad (8)$$

where the summation is over the residues in the protein, the superscripts indicate observed and calculated parameters, and σ is the standard error in the measured parameter. A single value of τ_m is assigned to all residues in the protein and then the set of $\{S_i^2, \tau_{ei}\}$ values that minimize χ^2 is found using conjugate gradient minimization.²⁵ This process is repeated, incrementing τ_m until the minimum value of χ^2 is attained. Then, several hundred synthetic data sets are used in a Monte Carlo approach^{23,26,29} to determine the uncertainties in the model-free parameters.

In analyzing relaxation data, residues that have unusually small T_2 values should be noted, because a small T_2 suggests that chemical exchange contributes to transverse relaxation. In contrast, unusually large T_2 values indicate the presence of large-amplitude, rapid internal motions that may not be well fit by a single internal correlation time. It is probably best to exclude residues with unusual T_2 values from the initial determination of τ_m using equation (8). Once the value of τ_m is determined, residues having anomalous T_2 values can be analyzed to see if an exchange term is required to account for a small T_2 or if an analysis involving more than one internal correlation time is required to account for relaxation data of residues having large T_2 values. An approach has been presented,²⁹ based upon statistical criteria, for systematically adding parameters to analyze relaxation data within the framework of the model-free formalism.

4 TWO-DIMENSIONAL HETERONUCLEAR RELAXATION STUDIES OF PROTEINS

4.1 Staphylococcal Nuclease (SNase)

Staphylococcal nuclease is a 17 kDa phosphodiesterase that efficiently hydrolyzes strands of both DNA and RNA. Relaxation studies of a uniformly ^{15}N -labeled protein yielded an overall correlation time of 8.3–8.5 ns,³⁰ while ^{13}C relaxation measurements³¹ of samples labeled at alanine (Ala) C- α sites yielded a somewhat larger value of τ_m in the range 9.2–9.5 ns. The larger value of τ_m , obtained from the carbon relaxation data has been ascribed to the fact that the viscosity of the solvent (D_2O) is about 20% greater than the solvent (H_2O) used in the ^{15}N study. The residue-specific order parameters of the Ala ^{15}N amide and C- α sites were in good agreement. Moreover, values of S^2 were in the range 0.8–0.95 for nearly all amino acids in the protein. This result showed that internal motion of the SNase backbone is limited to rapid small-amplitude

motions. Exceptions to this statement are (a) highly flexible residues in the N- and C-termini which have large T_2 values, and (b) several residues in the functionally important Ω loop which have unusually small T_2 values. In the X-ray structure of SNase³² residues in the Ω loop have weak electron density and large B factors. In solution, the loop is highly flexible, as evidenced by the broad lines and missing amide signals of residues in, or adjacent to, the loop. Although the Ω loop is flexible, it has a significant role in catalysis, as constructs of SNase lacking the loop have virtually the same structure as the parent molecule, but significantly lower levels of activity.

Although the side chains of all 11 leucine (Leu) residues in SNase are in well-structured regions of the protein, the values of S^2 of the Leu methyl sites fall into two distinct classes.^{23,30} In the presence of stabilizing ligands, thymidine 3',5'-bisphosphate and Ca^{2+} , four residues have values of S^2 , approx. 0.4–0.5, that are substantially less than the values of S^2 , approx. 0.8–0.9, of six of the remaining residues. This result indicates that there is a significant range in the flexibility of the large, hydrophobic side chains in SNase. Furthermore, it was found that the flexibility of the Leu methyl groups was sensitive to ligand binding, with side chains in the neighborhood of the ligand binding sites increasing in flexibility in the absence of the ligands.

4.2 Calmodulin and Calbindin D_{9k}

Calmodulin is a 148-residue protein that couples fluctuations in Ca^{2+} concentration to cellular activity. In the crystalline state the protein has the shape of a dumbbell in which two globular domains are connected by a continuous 26-residue α -helix. However, a ^{15}N relaxation study has shown that residues in the center of this helix have small order parameters, in the 0.5–0.6 range.³³ In addition, the relaxation data showed that the N- and C-terminal globular domains tumble nearly isotropically with slightly different correlation times. These results are strong evidence that the central helix is flexible in solution, a result that structural studies of the calmodulin/M19 complex have confirmed.³⁴

Calbindin D_{9k} is a 75-residue member of the calmodulin superfamily of calcium-binding proteins, containing two calcium binding sites. A careful comparison of ^{15}N relaxation measurements³⁵ made on the apo protein, the protein with Ca^{2+} in binding site II, and the protein with ions in both sites I and II, has shown that ion binding has very small effects on amide order parameters, with the notable exception of residues in binding site II. The order parameters of these residues increase from 0.6 to 0.85 when an ion is bound in site II. In contrast, residues in site I have large order parameters, S^2 approx. 0.8–0.85, in the absence and presence of bound ions. The asymmetry in the dynamic behavior of the two Ca^{2+} binding sites may be related to the fact that site I is not a typical EF hand (Ca^{2+} -binding loop), and is being characterized by further work on protein samples, half saturated with Ca^{2+} .

4.3 Interleukins, IL-1 β , IL-4, and IL-8

High-resolution crystal and solution structures, as well as backbone amide order parameters are available³⁶ for IL-1 β , IL-4, and IL-8. Analysis of these extensive data has

shown that amide nitrogen order parameters correlate with the inverse of (a) rms deviation (rmsd) values of the amide nitrogen coordinates, derived from the NMR structures, and (b) the amide nitrogen crystallographic B factors. While the correlations show significant scatter, this is to be expected because internal motions on a timescale slower than τ_m will not usually affect S^2 but will affect the other two parameters. Furthermore, crystal contacts may hinder motions that occur in solution. In general, it was found that amide nitrogen sites, having small B factors and small rmsd values in NMR structures, are strongly correlated with amide nitrogen sites that have large values of S^2 .

4.4 Bovine Pancreatic Trypsin Inhibitor, BPTI

Bovine pancreatic trypsin inhibitor (BPTI) was one of the first proteins whose internal dynamics were characterized by NMR lineshape and relaxation studies. More recently, measurement of transverse relaxation rates using natural abundance two-dimensional ^1H – ^{13}C heteronuclear techniques has provided evidence for slow internal motions involving cysteine (Cys) 14 and Cys-38.¹⁰ A thorough investigation of this process in wild-type BPTI and in a mutant protein, BPTI(G36S), showed that the protein is an equilibrium mixture of interconverting isomers of the Cys-14–Cys-38 disulfide bond.³⁷ The rate of interconversion of the two isomers, as determined by measurements of the ^{15}N $T_{1\rho}$ of Cys-38 and of Arg-39, as a function of the spin lock field,³⁸ was in reasonable agreement with the rate of conformational exchange determined independently using two-spin-order exchange experiments and from measurements of chemical exchange line broadening. This work also demonstrates that, because of the inherent limited sensitivity of protein NMR spectra, slow dynamic processes in proteins are difficult to observe and may be more common than has been supposed.

5 SUMMARY OF ^{15}N WORK AND PROSPECTS FOR ^{13}C MEASUREMENTS

Unfortunately, space does not permit even brief individual reviews of the substantial number of other interesting proteins that have been studied using ^{15}N relaxation measurements. However, a few general comments about backbone mobility, based upon the ^{15}N relaxation work, can be made. Internal motions of the amide backbone are small in amplitude, with order parameters typically greater than 0.8 for amino acids in regions of regular secondary structure. In contrast, residues in either the terminal regions of the protein sequence or in small external loops often exhibit large amplitude, $S^2 < 0.6$, rapid internal motions, with $\tau_e \ll \tau_m$. Much slower motions, on the chemical shift timescale, are most commonly seen for large loops or segments near the protein surface, that often contain amino acid residues implicated in the function of the molecule.

While the ^{15}N studies have provided the first comprehensive view of internal dynamics of the protein backbone in solution, internal motions of protein side chains are likely to be considerably more varied and interesting. While the use of specifically ^{13}C -labeled samples is a means of studying such

motions, it would be much more efficient to use uniformly ^{13}C -labeled samples, provided that the pulse sequences can be developed that suppress effects of carbon–carbon coupling. Labeling a protein with ^{13}C at alternate carbon sites has also been proposed³⁹ to achieve this goal. Elimination of the effects of dipolar cross correlation ^{13}C relaxation measurements is also highly desirable. This has been done for glycine (Gly) C- α H $_2$ sites in *Escherichia coli* thioredoxin by preparing a sample labeled with 50% [$\text{U-}^2\text{H}$, 2- ^{13}C]Gly,³⁹ and recording spectra using pulse sequences that (a) select for Gly α -carbons bonded to a single proton, and (b) decouple deuterons. Deuteration also has the advantage that both carbon and proton T_2 values are significantly larger than in the protonated protein. Although it will require considerably more effort to measure relaxation parameters of protein uniformly labeled with ^{13}C than with ^{15}N , the wealth of information about protein side-chain motions that will be provided by the ^{13}C experiments should fully reward the effort required.

1 INTRODUCTION

In the last decade, NMR spectroscopy has become an important alternative to X-ray crystallography for the structural studies of molecules of biological interest. The principal advantage of NMR is that it allows the study of biomolecules in solution, thus closer to their real physiological environment. The method is limited, however, to biomolecules of relatively small size due to limitations in spectral resolution and line-broadening effects. The upper limit is presently situated around molecular weights of 30 kDa. Knowledge of three-dimensional (3D) structures might lead, for example, to a better understanding of structure–function relationships or recognition processes. For this purpose, accurate structures are required and, as we shall see, the use of so-called relaxation matrix approaches provides a means of improving the accuracy of the method.

The process of structure determination based on NMR data can be divided into four stages:

1. assignments of the proton resonances,
2. determination of structural constraints from NOE and J coupling data,
3. generation of structures,
4. refinement of these structures.

The first and laborious task of assigning proton resonances is still the main bottleneck of the structure determination, but progress is being made in this area by the development of new multidimensional NMR techniques [3D and four-dimensional (4D)]^{1–6} and the use of labeled samples (¹⁵N, ¹³C). Computational approaches are also being developed toward an automatic assignment of the NMR spectra (see *Analysis of Spectra: Automatic Methods*). We will not treat this aspect of the problem here, but concentrate on the last three stages involving the determination of structural constraints (distances, dihedral angles) and the generation and refinement of the structures.

Structure determination by NMR is based primarily on the nuclear Overhauser effect (NOE)⁷ (see *Nuclear Overhauser*

Effect). Its origin is dipolar cross relaxation between protons, which is a function of distances and molecular motions. Because of the approximate r^{-6} dependence of the NOEs on the interproton distances, these can only be measured between protons relatively close in space (< about 0.5 nm). NOEs are generally transformed into distance constraints which are then used, together with dihedral angle constraints obtained from J coupling data, for the generation of structures using Distance Geometry (DG)⁸ (see *Distance Geometry*) or Simulated Annealing (SA) techniques.^{9,10} These structures are then usually refined with a combination of restrained Energy Minimization and Molecular Dynamics (MD) simulations.¹¹ Genetic algorithms¹² and heuristic methods based on Kalman filter techniques¹³ can also be used for this purpose. Several approaches have been proposed for the interpretation of NOEs in terms of distances. The simplest one classifies the NOEs into strong, medium, and weak peaks and attributes corresponding distance ranges to these three categories. However, more accurate distances can be obtained from relaxation matrix calculations, which take into account all indirect magnetization transfers ('spin diffusion').^{14–23} A more direct method for refinement was proposed by Yip and Case,²⁴ in which NOE intensities are directly used as structural constraints, thus avoiding the transformation into distances. In this method, the structures are directly refined against experimental NMR data by comparison of theoretical and experimental NOE intensities.

In addition to NOEs and J couplings, chemical shifts can also provide structural information on biomolecules. Recent developments that permit the prediction of ¹H, ¹³C, ¹⁵N, and ¹⁹F chemical shifts should open new avenues to the structure refinement of proteins^{25–29} (see *Amino Acids, Peptides and Proteins: Chemical Shifts; Chemical Shifts in Biochemical Systems*).

In this review, we will first discuss the underlying theory of the NOE, including a description of intramolecular motions. The use of NOEs as structural constraints, indirectly by conversion into distances or directly by comparison of experimental and theoretical intensities, will be presented together with the most common methods used to generate and refine structures. This will be illustrated with results from our laboratory for the structure determination and refinement of the Arc repressor of phage P22, a dimeric DNA-binding protein (2 × 53 residues).

2 THE NUCLEAR OVERHAUSER EFFECT

2.1 Relaxation Matrix Theory

Multispin relaxation in a biomolecule in solution can be approximately described by the generalized Bloch equations. The evolution of the longitudinal magnetization components in a system of N spins is governed by a set of coupled differential equations of the form³⁰

$$\frac{d}{dt}\Delta\mathbf{M}(t) = -\mathbf{R}\Delta\mathbf{M}(t) \quad (1)$$

where the vector $\Delta\mathbf{M}(t)$ comprises the deviations from thermal equilibrium for all spins i

$$\Delta M(t)_i = [M_z(t) - M_0]_i \quad (2)$$

and $\mathbf{R}$ is the relaxation matrix. It comprises contributions from cross relaxation and from external relaxation. For a system of dipolar-coupled spins, neglecting cross correlation, $\mathbf{R}$ has the dimension of the number of spins N in the systems. Since the dipolar interaction is a function of time, the relaxation rates are intimately connected with the molecular motion. The elements of $\mathbf{R}$ can be expressed as^{7,30}

$$\begin{aligned} R_{ii} &= \rho_{ii} = K \sum_{j \neq i} [J_{ij}^0(0) + 3J_{ij}^1(\omega_0) + 6J_{ij}^2(2\omega_0)] + R_{\text{leak}} \\ R_{ij} &= \sigma_{ij} = K[-J_{ij}^0(0) + 6J_{ij}^2(2\omega_0)] \end{aligned} \quad (3)$$

where ω_0 is the Larmor frequency and $K = (2\pi/5)\gamma^4\hbar^2$; ρ_{ii} is the auto relaxation rate, with R_{leak} as an additional term to account for all nondipolar relaxation mechanisms, and σ_{ij} is the cross-relaxation rate between spins i and j . $J_{ij}^m(\omega)$ denotes the spectral densities at multiple values of the spin Larmor frequency $[(m \times \omega_0)]$ with $m = 0, 1, 2$. Cross relaxation is normally measured by observing intensity changes upon saturation or inversion of spins. Two-dimensional (2D) NMR techniques have been developed to investigate the resulting NOEs³¹ (see *Nuclear Overhauser Effect; NOESY*). The integrated intensities I_{ij} in a 2D NOE spectrum recorded with mixing time τ_m , are given by the matrix equation³¹

$$\mathbf{I}(\tau_m) = \exp(-\mathbf{R}\tau_m)\mathbf{M}(0) = \mathbf{A}\mathbf{M}(0) \quad (4)$$

which is the formal solution of the differential equation (1) where $\mathbf{M}(0)$ specifies the starting conditions. This defines the exponential matrix of normalized NOE intensities $\mathbf{A}$,

$$\mathbf{A} = \exp(-\mathbf{R}\tau_m) \quad (5)$$

that will be referred to as ‘the NOE matrix’.

The spectral densities $J_{ij}^m(\omega)$ in the definitions of the relaxation rates ρ_{ii} and σ_{ij} are cosine Fourier transforms

$$J_{ij}^m(\omega) = \int_0^\infty C_{ij}^m(t) \cos(\omega t) dt \quad (6)$$

where the $C(t)$ are correlation functions describing the time evolution of the dipolar interaction. Assuming that the molecule is a rigid body moving isotropically in solution, the correlation functions in equation (6) can be described by a simple exponential of the form $\exp(-t/\tau_c)$, τ_c being the correlation time for the overall rotation of the molecule. With this simple definition, the spectral density $J_{ij}^m(\omega)$ becomes

$$J_{ij}^m(\omega) = \frac{1}{4\pi r_{ij}^6} \left[\frac{\tau_c}{1 + (\omega\tau_c)^2} \right] \quad (7)$$

If the assumption of a rigid body is not valid, which is usually the case for biomolecules, the description of $C(t)$ by a simple exponential is no longer correct. The correlation function should then be defined in a more general form as

$$C_{ij}^m(t) = \left\langle \frac{Y_{2m}[\Phi_{ij}^{\text{lab}}(t_0 + t)] Y_{2m}^*[\Phi_{ij}^{\text{lab}}(t_0)]}{r_{ij}^3(t_0 + t) r_{ij}^3(t_0)} \right\rangle \quad (8)$$

Here the angular brackets indicate a time average over t_0 (which is equivalent to an ensemble average); Y_{2m} are the

second-order spherical harmonics and r and Φ^{lab} denote the length and polar angles of the interproton vector in the laboratory frame of coordinates. The form of the spectral density functions $J_{ij}^m(\omega)$ could be obtained experimentally from relaxation measurements. The feasibility of this approach has been recently demonstrated by Peng and Wagner^{32,33} who mapped the spectral densities of N–H vectors using heteronuclear relaxation experiments. In theory, this function can also be computed from a long MD trajectory. With present-day computational facilities $C(t)$ can only be computed with sufficient statistical accuracy for t values of the order of 0.1–1.0 ns. Fortunately, for many interproton vectors $C(t)$ is observed to reach a plateau value after a few ps, indicating that fast picosecond motions are well separated from slower processes.^{34,35}

Following the approach developed by Lipari and Szabo,^{36,37} a ‘model-free’ description of $C(t)$ can be set up in terms of two characteristic times, τ_p , the time in which $C(t)$ decays to the initial plateau value due to the fast internal motions, and τ_c , the correlation time for the overall rotation of the molecule. Assuming isotropic tumbling, and transforming to molecule fixed coordinates Φ^{mol} one has³⁴

$$C_{ij}^m(t) = \frac{\exp(-t/\tau_c)}{4\pi} C_{ij}^{\text{int}}(t) \quad (9)$$

where the internal motion correlation functions $C^{\text{int}}(t)$ are defined as

$$C_{ij}^{\text{int}}(t) = \frac{4\pi}{5} \sum_{n=-2}^2 \left\langle \frac{Y_{2n}[\Phi_{ij}^{\text{mol}}(t_0 + t)] Y_{2n}^*[\Phi_{ij}^{\text{mol}}(t_0)]}{r_{ij}^3(t_0 + t) r_{ij}^3(t_0)} \right\rangle \quad (10)$$

According to the addition theorem $C_{ij}^{\text{int}}(0) = \langle r_{ij}^{-6} \rangle$. The plateau value of the correlation function, $C_{ij}^{\text{int}}(t)$, can thus be defined quite generally as $S_{ij}^2 \langle r_{ij}^{-6} \rangle$, where S_{ij}^2 is a generalized order parameter. It has a value between 0 and 1, and can be calculated from an MD trajectory by using equation (10) and estimating the plateau value for each interproton vector. Within this simplified model the functions $C_{ij}^{\text{int}}(t)$ can be written as

$$C_{ij}^{\text{int}}(t) = \left\langle \frac{1}{r_{ij}^6} \right\rangle [S_{ij}^2 + (1 - S_{ij}^2) \exp(-t/\tau_p)] \quad (11)$$

where the initial decay has been written as an exponential. Combining equations (6) and (8)–(11), one arrives at^{34,35}

$$J_{ij}^m(\omega) = \frac{1}{4\pi} \left\langle \frac{1}{r_{ij}^6} \right\rangle \left[\frac{S_{ij}^2 \tau_c}{1 + (\omega\tau_c)^2} + \frac{(1 - S_{ij}^2) \tau_{\text{cp}}}{1 + (\omega\tau_{\text{cp}})^2} \right] \quad (12)$$

with $\tau_{\text{cp}}^{-1} = \tau_c^{-1} + \tau_p^{-1}$. Assuming that $\tau_p \ll \tau_c$, the second term in equation (12), related to the initial decay, vanishes and $J_{ij}^m(\omega)$ becomes

$$J_{ij}^m(\omega) = \frac{1}{4\pi} \left\langle \frac{1}{r_{ij}^6} \right\rangle \frac{S_{ij}^2 \tau_c}{1 + (\omega\tau_c)^2} \quad (13)$$

Besides the effects of fast local motions, other dynamic processes like, for example, methyl group rotation and aromatic ring flips can affect the relaxation behavior of

biomolecules. Their inclusion in the calculation of the theoretical NOE intensities has been described in detail by Koning et al.³⁸

2.2 Computational Aspects

Basically two methods are available for the computation of theoretical NOE intensities. These have been reviewed by Forster.³⁹ The first involves finding the eigenvectors and eigenvalues of the real symmetrical matrix $\mathbf{R}$ by standard matrix techniques.¹⁴

$$\Lambda = \mathbf{X}^{-1}\mathbf{R}\mathbf{X} \quad (14)$$

Combining this expression with equation (5) leads to

$$\mathbf{A} = \exp(-\mathbf{R}\tau_m) = \mathbf{X}\exp(-\Lambda\tau_m)\mathbf{X}^{-1} \quad (15)$$

The matrix diagonalization scales as N^3 , where N is the dimension of the matrix $\mathbf{R}$, and can become extremely time-consuming when N increases. The calculations can be speeded up by making use of the sparseness of the relaxation matrix; due to the r^{-6} dependence on the distances of the cross-relaxation rates, only a few elements of $\mathbf{R}$ are significantly larger than zero. Thus, it is possible to apply a spherical cutoff around each proton pair defining a subset of NOEs with only the neighbors. In this way, for each peak, a small eigenvalue problem can then be solved. The second approach⁴⁰ for the calculation of theoretical intensities is based on a numerical integration of the differential equations [equation (1)] describing the time dependence of the NOE intensities. Several integration schemes exist (Taylor series integration, Euler algorithm, various Runge–Kutta methods) and their accuracy and performance have been addressed by Forster.³⁹ A choice between the various methods has to be made depending on the dimension of the system and on the purpose of the NOE calculation; for example, numerical integration is no longer suitable if eigenvalues and/or eigenvectors are required (e.g. for the analytical NOE gradient; see Section 2.4).

2.3 From NOEs to Distances

2.3.1 Two-Spin Approximation

Proton–proton distance constraints are most conveniently derived from cross-peak intensities in 2D NOE spectra taken at various short mixing times. The initial buildup rate of these peaks is proportional to the cross-relaxation rates σ_{ij} between protons i and j .⁴¹ Therefore, these cross-relaxation rates can be measured either from a single 2D NOE spectrum taken with a sufficiently short mixing time or, more accurately, from a buildup series recorded with various mixing times.^{41–43} For a large molecule, assuming isotropical tumbling and no internal motions, the $J_{ij}^0(0)$ term in equation (3) dominates the cross-relaxation rate σ_{ij} which becomes simply related to the distance r_{ij} and the correlation time τ_c :

$$\sigma_{ij} \propto -\tau_c r_{ij}^{-6} \quad (16)$$

Therefore, with a known calibration distance r_{cal} , the proton–proton distances follow from the relationship

$$r_{ij} = r_{\text{cal}}(\sigma_{\text{cal}}/\sigma_{ij})^{1/6} \quad (17)$$

In practice equations (16) and (17) are only approximately valid. There are two main problems associated with accurate determination of proton–proton distances. The first is that proteins are not rigid bodies, and intramolecular mobility leads to nonlinear averaging of distances and to different effective correlation times for the different interproton vectors in the molecule. The second is that of indirect magnetization transfer or ‘spin diffusion’.⁴⁴ In reality the NOE cross peaks are the result of multispin relaxation and only in the limit of extremely short mixing times (where the signal-to-noise ratio is poor) is the two-spin approximation of equation (16) valid. For these reasons, a common approach is that of translating the NOE intensities into distance ranges (e.g. 0.2–0.3, 0.2–0.4, 0.2–0.5 nm for strong, medium, and weak NOEs, respectively) rather than attempting to obtain precise distances.⁴⁵

It has become possible to circumvent the spin diffusion problem by the use of relaxation matrix calculations, which take into account all indirect magnetization transfers. These methods will be developed in the next section.

2.3.2 Relaxation Matrix Approaches

When a model for the structure and dynamics of a molecule is available, the NOEs can be calculated from the spectral densities as shown above [see equations (3), (5), (14), and (15)]. The opposite route from experimental NOEs to relaxation parameters is also possible. The relaxation matrix $\mathbf{R}$ can be obtained after diagonalization of the NOE matrix $\mathbf{A}$.¹⁵

$$\mathbf{X}^{-1}\mathbf{A}\mathbf{X} = \mathbf{D} = \exp(-\Lambda\tau_m) \quad (18)$$

$$\mathbf{R} = -\mathbf{X}\left(\frac{\ln \mathbf{D}}{\tau_m}\right)\mathbf{X}^{-1} \quad (19)$$

Thus, theoretically the matrix $\mathbf{R}$ can be obtained directly from 2D NOE experiments taken at suitably chosen mixing times. In practice, this is not possible for large molecules, since the experimental NOE matrix is incompletely known due to overlap and missing assignments. Hybrid matrix methods have been proposed to circumvent this problem, in which the experimental data are supplemented by theoretical NOEs calculated from a model structure as implemented in IRMA,^{16,17} MARDIGRAS,¹⁸ MORASS,⁴⁶ FIRM,²² and CROSREL.²³ An overview of the Iterative Relaxation Matrix Approach (IRMA) is given in Figure 1.

The starting point for the calculations can be a single structure or an ensemble of structures, the relaxation matrix being built from the distances of the corresponding contributions averaged as $\langle r^{-6} \rangle$ in the latter case. A theoretical NOE matrix is then computed using standard matrix techniques [cf. equation (14) and equation (15)] and combined with the experimental data. The resulting matrix can then be transformed back to a corrected relaxation matrix from which new distances are calculated. These distances are used to generate an improved model. The whole process is repeated until convergence is obtained. In other implementations (MARDIGRAS, MORASS, FIRM), the theoretical information is progressively introduced in the hybrid matrix and the back-calculated corrected relaxation matrix is directly used to calculate new NOE

The derivative of A_{ij} with respect to the relaxation matrix element R_{kl} is defined as:

$$\frac{\partial A_{ij}}{\partial R_{kl}} = \lim_{h \rightarrow 0} \frac{A(\mathbf{R} + \mathbf{D})_{ij} - A(\mathbf{R})_{ij}}{h} \quad (24)$$

where $A(\mathbf{R} + \mathbf{D}) = \exp[-(\mathbf{R} + \mathbf{D})\tau_m]$ and $\mathbf{D}$ is a perturbation of $\mathbf{R}$ whose only nonvanishing component is h . By using standard quantum-mechanics perturbation expansion techniques one can identify the NOE matrix $\mathbf{A}$ as the evolution operator, the relaxation rate matrix $\mathbf{R}$ as the Hamiltonian, and τ_m as the imaginary time i . $A(\mathbf{R} + \mathbf{D})_{ij}$ can then be approximated to first-order in h as

$$A(\mathbf{R} + \mathbf{D})_{ij} = A(\mathbf{R})_{ij} - h \int_0^{\tau_m} \exp[-\mathbf{R}(\tau_m - s)]_{ik} \exp(-\mathbf{R}s)_{lj} ds \quad (25)$$

Substituting this expression in equation (23) gives the derivative of the NOE with respect to R_{kl} :

$$\frac{\partial A_{ij}}{\partial R_{kl}} = - \int_0^{\tau_m} \exp[-\mathbf{R}(\tau_m - s)]_{ik} \exp(-\mathbf{R}s)_{lj} ds \quad (26)$$

The integral in equation (26) can be computed efficiently with numerical integration techniques. In addition, since no eigenvectors of $\mathbf{R}$ are required as for the expression in equation (21) any technique that allows a fast and accurate evaluation of the NOE intensities can be used in place of the diagonalization method. The derivative in equation (26) has been shown to be equivalent to the analytical expression proposed by Yip and Case²⁴ [equation (21)] and, from preliminary results, appears to be significantly faster than the expression in equation (21).⁶¹

2.4.2 3D NOE–NOE Intensities

For larger molecules considerable overlap can exist in 2D spectra. This overlap can be overcome by spreading the peaks in a third dimension and new multidimensional NMR techniques were therefore developed.^{1–6} A similar procedure as with the refinement of NOE data from one-dimensional and 2D spectra can be followed for the treatment of NOE intensities from 3D spectra.

The intensities of cross peaks in a 3D spectrum are proportional to the transfer efficiencies of the two mixing periods of the experiment. The net transfer can be described in general as:

$$T_{ijk}^{3D} = T_{ij}(1)T_{jk}(2) \quad (27)$$

where $T_{ij}(1)$ and $T_{jk}(2)$ describe the magnetization transfer efficiencies for each separate mixing period and correspond to NOE transfer, exchange, or J transfer. The use of cross-peak intensities in a structure refinement procedure requires calculation of the gradients of these 3D intensities with respect to the coordinates of the protons in a molecule. The gradient of a 3D peak can be written as the sum of two terms containing the separate gradients of $T_{ij}(1)$ and $T_{jk}(2)$:

$$\nabla T_{ijk}^{3D} = T_{jk}(2)\nabla T_{ij}(1) + T_{ij}(1)\nabla T_{jk}(2) \quad (28)$$

These equations can be generalized for even higher dimensional experiments. Thus, given a valid model for the calculation of the magnetization transfer efficiencies and their derivatives, 3D peaks can be used as constraints in a direct refinement procedure.

In particular, 3D NOE–NOE spectra appear to be suitable for this purpose. This latter technique was developed for the direct observation of indirect NOE magnetization transfer ('spin diffusion') as occurs in larger biomolecules.⁶² Kessler et al.⁶³ and Habazettl et al.⁶⁴ described the quantitative use of 3D NOE–NOE cross peaks for obtaining distance constraints, which are used by DG or restrained MD computations. It is also possible to use the intensities of such 3D spectra as direct constraints for structure refinement.⁶⁵ In a 3D NOE–NOE spectrum the 3D cross-peak intensities A_{ijk}^{3D} can be calculated from their separate 2D NOE transfer efficiencies. The computation of the 3D NOE–NOE intensity A_{ijk}^{3D} then amounts to the multiplication of the calculated 2D contributions A_{ij} and A_{jk} . A similar NOE restraining potential function can be defined as for the direct refinement with 2D NOE data.⁶⁵ The same approximations as for 2D data can be used for the computation of the 3D NOE–NOE forces.

The feasibility of direct NOE refinement with 3D NOE–NOE data was demonstrated by Bonvin et al.⁶⁵ for a small peptide with synthetic 3D data using a simple approximation for the derivative of the NOE intensity based on the first two terms of the expansion of the exponential function [equation (23)].⁶⁵ A similar approach has been developed since by Habazettl et al.⁶⁶ and applied to the structure refinement of a few proteins [*Cucurbita maxima* trypsin inhibitor I (CMTI-I), hisactophilin, mucous protease inhibitor (MPI)].^{66,67} The main problem with the application of the method lies in the assignment of cross peaks of a 3D NOE–NOE spectrum. The huge amount of data contained in a 3D experiment requires an efficient program for automatic assignment and peak-picking before a refinement based on 3D NOE–NOE intensities can be undertaken.

3 STRUCTURE CALCULATIONS

3.1 Distance Geometry (DG)

The metric matrix DG algorithm^{68,69} was known well before structure determination by NMR became possible.^{70,71} This method does not rely on a starting conformation, is free from operator bias in this respect, and is therefore very attractive for structure determination. The DG procedure amounts to the following. First, upper and lower bound matrices $\mathbf{U}$ and $\mathbf{L}$ are set up for all atom–atom distances of the molecule. Some of the elements u_{ij} and l_{ij} follow from standard bond lengths and bond angles of the covalent structure and from experimentally found distance ranges from NOEs and J coupling constants. A bound smoothing procedure using triangle inequalities extends the constraints to all elements of $\mathbf{U}$ and $\mathbf{L}$. This procedure can even be extended to satisfy tetrahedron inequalities as for example implemented in the DG-II package⁸ (see **Distance Geometry**). Then, a distance matrix $\mathbf{D}$ is set up with distances chosen randomly between upper and lower bounds, $l_{ij} \leq d_{ij} \leq u_{ij}$. The elements of $\mathbf{D}$ can be chosen in such a way that they not only lie between their respective upper and lower

bounds, but also themselves obey the triangle inequalities; this latter technique is known as *random metrization*. The so-called ‘embedding’ algorithm then finds the best 3D structure consistent with the distances d_{ij} . This structure must be optimized with an error function consisting of chirality and distance constraints. This forces the amino acid side chains to adopt the correct chirality and the distances to satisfy the upper and lower bound criteria, although usually the DG structures still contain a number of violations of the distance bounds. By repetition of the DG calculations with randomly chosen distance matrices $\mathbf{D}$, families of structures can be obtained that allow one to judge how uniquely the structure is determined by the constraints.

Another method, also termed distance geometry, but using a quite different mathematical procedure, was suggested by Braun and Gö. ⁷² Here, the biomolecular conformation is calculated by minimizing a distance constraint error function. Special features of the method are that dihedral angles are used as independent variables rather than Cartesian coordinates and that it uses a variable target function, first satisfying local constraints (between amino acids nearby in the polypeptide chain) and later including long-range constraints. This approach avoids becoming trapped in a local minimum of the target function. Usually one starts with various initial conformations obtained by taking random values for the dihedral angles. This method, which has been implemented since in various programs, e.g. DISMAN ⁷² and more recently DIANA, ⁷³ has rather similar efficiency and convergence properties as the metric matrix distance-geometry algorithm.

3.2 Simulated Annealing (SA)

Although the DG methods do not need starting structures and are therefore not subject to operator bias, this does not mean that they sample the allowed conformational space (consistent with the bounds) in a truly random fashion. Simplified MD calculations with only geometric constraints were developed to increase the sampling of the DG methods. These are termed, in general, simulated annealing (SA) procedures. Although these can be directly used to generate structures starting from random coordinates, they are most commonly combined with DG calculations, the starting structures for the SA stage being obtained by DG embedding. Simulated annealing involves raising the temperature of the system followed by slow cooling in order to overcome local minima and locate the region of the global minimum of the target function V_{tot} (cf. Nilges et al.) ⁹. This is achieved by solving Newton’s equations of motion

$$m_i \ddot{\mathbf{r}}_i = \mathbf{F}_i \quad (29)$$

with the forces given by

$$\mathbf{F}_i = -\partial V_{\text{tot}} / \partial \mathbf{r}_i \quad (30)$$

The potential V_{tot} usually contains the following terms:

$$V_{\text{tot}} = V_{\text{covalent}} + V_{\text{repel}} + V_{\text{disre}} + V_{\text{dihre}} + V_{\text{NOE}} \quad (31)$$

V_{covalent} is a potential to maintain correct bond lengths, angles, planes and chirality, V_{repel} is a simple repulsion term to prevent unduly close nonbonded contact, V_{disre} and V_{dihre} represent

the experimental NOE distance and dihedral angle constraints, respectively, and V_{NOE} is an extra term for direct comparison of theoretical and experimental NOE intensities as defined in equation (20). Usually the NOE distance constraints are represented by a flat well potential of the form

$$V_{\text{disre}} = \begin{cases} \frac{1}{2} K_{\text{disre}} (d_{ij} - l_{ij})^2 & 0 \leq d_{ij} \leq l_{ij} \\ 0 & l_{ij} \leq d_{ij} \leq u_{ij} \\ \frac{1}{2} K_{\text{disre}} (d_{ij} - u_{ij})^2 & u_{ij} \leq d_{ij} \end{cases} \quad (32)$$

where l_{ij} and u_{ij} are the value of lower and upper limits of the target distances, respectively. Other forms that contains a linear part at long distances are also used ⁷⁴ to avoid too large energies, which may give computational problems. A similar definition as in equation (32) can be used for dihedral angle constraints, but other forms have also been proposed such as: ⁷⁵

$$V_{\text{dihre}} = K_{\text{dihre}} [1 - \cos(\phi - \phi_0)] \quad (33)$$

where ϕ_0 represents the dihedral angle value obtained from J coupling data. The various terms in equation (31) have variable force constants, which can be progressively increased during the annealing.

The combination of DG, for generating starting structures with an approximate folding by embedding a subset of atoms, and SA calculations, provides a powerful and efficient tool for the structure determination of biomolecules. ^{9,76} This hybrid method should be particularly useful for solving the structure of large proteins for which computational costs may become a limiting factor.

3.3 Restrained Molecular Dynamics and Energy Minimization (RMD, REM)

The quality of biomolecular structures based on geometric constraints can be improved by taking energy considerations into account. For instance, in DG structures amino acid side chains often adopt eclipsed conformations. Also, hydrogen bonds and salt bridges may not be formed unless they are specifically introduced as constraints. In RMD refinement structures are optimized simultaneously with respect to a potential energy function and a set of experimental restraints. Of course the success of this method now depends to a large extent on the quality of the force field used. It is therefore important to realize the limitations and approximate nature of this force field, especially when the calculations do not include solvent molecules.

In RMD calculations, equation (29) and equation (30) are integrated with the potential function given by

$$V_{\text{tot}} = V_{\text{bond}} + V_{\text{angle}} + V_{\text{torsion}} + V_{\text{vdW}} + V_{\text{Coulomb}} + V_{\text{disre}} + V_{\text{dihre}} + V_{\text{NOE}} \quad (34)$$

The first two terms tend to keep bond lengths and angles at their equilibrium values. V_{torsion} is a sinusoidal potential describing rotations about bonds; for V_{vdW} (the van der Waals interaction) usually a Lennard–Jones potential is taken, and V_{Coulomb} describes the electrostatic interactions. The three last

terms, similar to those in equation (31), distinguish RMD from more conventional MD simulations.

An RMD simulation is usually preceded and followed by REM using steepest descent or conjugated gradient methods to bring the energy down to an acceptable level. Using the same potential energy function as RMD [equation (34)] REM usually induces only small changes in the structures by driving them to the closest minimum and is not able to take them out of this. By contrast, RMD is able to overcome barriers of the order of kT because of the kinetic energy in the system and therefore has a much larger radius of convergence. The RMD method works as an efficient minimizer, since excess potential energy, converted to kinetic energy, is drained off by coupling the system to a thermal bath of constant temperature. Sampling of the conformational space consistent with the experimental constraints can be increased by using high-temperature simulations⁷⁷ or potential energy annealing conformational search methods (PEACS)⁷⁸ in which the potential energy is coupled to a reference energy bath whose energy level is progressively decreased over the run, or by introducing a fourth dimension⁷⁹ as recently implemented in GROMOS (4D MD),⁸⁰ which, by increasing the number of degrees of freedom in the system, allows one to circumvent energy barriers present in the 3D potential energy hypersurface.

Further extensions of the method, especially useful for highly mobile structures, include time-averaging⁵⁴ or ensemble-averaging⁵⁵ of the experimental restraints. In these methods, V_{disre} is calculated from time- or ensemble-averaged distances instead of instantaneous ones. Forces are thus applied on the corresponding protons only if the *averaged* distance violates the restraint. These methods allow a larger conformational freedom consistent with the NOE restraints. The use of time-averaged restraints has recently been described for direct structure refinement with J coupling⁵⁶ and NOE⁵⁷ data.

4 QUALITY OF THE STRUCTURES

Important factors for assessing the quality of the NMR structures usually obtained with a combination of the above described methods are the number and distribution of the NOE and dihedral angle constraints and the number of stereospecific assignments. Several other criteria have also to be considered, but these will all depend, to some extent, on the factors mentioned above. The precision of the structure is generally given by the average root mean squared deviations (rmsd) (pairwise or from the average coordinates). These are usually calculated for the backbone and all atoms, respectively, and sometimes on a substructure. The rmsd as a function of the residue sequence can also be useful for identifying less well-defined regions in a structure. Another useful parameter to assess the precision of solution structures is the angular order parameter proposed by Hyberts et al.⁸¹

$$S_{\phi}^{\text{angle}} = \frac{1}{N_{\text{struc}}} \left[\left(\sum \cos \phi \right)^2 + \left(\sum \sin \phi \right)^2 \right]^{1/2} \quad (35)$$

It has the advantage that, contrary to rmsd, it does not require the superimposition of the structures. Angular order parameters (S^{angle}) are generally given as a function of

the residue sequence for backbone ϕ , ψ and side-chain χ_1 dihedral angles. S^{angle} values of 0.9 and 0.8, for example, indicate very well-defined dihedral angles with fluctuations of $\pm 24^\circ$ and $\pm 40^\circ$, respectively. We have to keep in mind, however, that the rmsd etc and angular order parameters give an indication of the precision of the structure, but are not a direct indication of its accuracy. Structures with very low rmsd can still be wrong! To judge the quality, we have to take several other criteria into account: the stereochemical quality (e.g. via ϕ , ψ Ramachandran plots), the deviations from the idealized covalent geometry, the conformational energy, residual restraints violations, the presence of hydrogen bonds, and a good packing of the structures; these are criteria commonly used for this purpose. Studies of the stereochemical quality of crystal and NMR protein structures have resulted in useful criteria to assess the quality of these structures.^{82,83} These criteria, among which are the percentage of residues in the favorable area of the Ramachandran plot and the χ_1 dihedral angles- and hydrogen-bond energy standard deviations, can be easily checked with the program PROCHECK,⁸² which allows a fast and simple evaluation of the stereochemical quality of a protein structure. Another criterion to assess the quality of the structures obtained from NMR data is directly to compare calculated and experimental NOEs. The fit can be described by a residual index or R factor in a similar manner as in X-ray crystallography. Several R factor definitions have been proposed^{47,84,85} and can all be represented by a general equation of the form:

$$R = \frac{\sum_i w_i |N_i^{\text{theo}} - N_i^{\text{exp}}|}{\sum_i w_i |N_i^{\text{ref}}|} \quad (36)$$

where $N_i = A_i$ or $N_i = (A_i)^{1/6}$ with, in the denominator, N_i^{ref} defined as $N_i^{\text{ref}} = N_i^{\text{exp}}$ or $N_i^{\text{ref}} = \frac{1}{2} (N_i^{\text{exp}} + N_i^{\text{theo}})$, w_i are weighting factors that can be chosen equal to the mixing times, since NOEs measured at longer mixing times are expected to have a better signal-to-noise ratio. The simplest one, with $N_i = A_i$ and $N_i^{\text{ref}} = N_i^{\text{exp}}$, is similar to the X-ray definition.⁸⁴ For NMR, however, other functions may be more appropriate since we are dealing principally with two problems. First, the range of NOE intensities is quite extended (by more than a factor of 1000) and R might be dominated by strong peaks, corresponding to short distances in the structures which are expected to be less important for determining the 3D structure. A sixth-root residual index, $R^{1/6}$, where $N_i = (A_i)^{1/6}$, allows for a more even contribution of weak and strong NOEs in the R factor.^{47,84} The second problem inherent to the R factor comes from the approximate r^{-6} dependence of the NOEs. Because of this extreme distance dependence, the R factor function is asymmetric, the error increasing strongly when the distances are shorter than the target distances. Normalizing the errors by the sum of both experimental and theoretical NOE intensities, $N_i^{\text{ref}} = \frac{1}{2} (N_i^{\text{exp}} + N_i^{\text{theo}})$, should avoid this problem.⁸⁵ To give a better picture of the quality of the structures, a distinction can be made between intra- and interresidue peaks and the R factors can be calculated as a function of the residue sequence, which allows one to recognize problem regions in the structures.

5 APPLICATION: THE ARC REPRESSOR

The structure refinement process using relaxation matrix calculations can be best illustrated using a specific example: the Arc repressor. The solution structure of the Arc repressor of *Salmonella* bacteriophage P22, a dimeric sequence-specific DNA-binding protein,⁸⁶ has been determined from 2D NMR data using an ‘ensemble’ IRMA followed by direct NOE refinement with DINOSAUR.⁸⁷

An 824 NOE buildup series in H₂O and D₂O and 130 additional qualitative distance constraints were collected for Arc. This resulted in a set of 954 constraints consisting of 350 intraresidue, 215 sequential, 181 medium range, and 208 long-range constraints; 144 of the total set correspond to intermonomer constraints. Twenty-four hydrogen bonds were also explicitly defined. The constraints were duplicated to account for the dimeric nature of Arc giving a total set of 2004 constraints (NOEs + hydrogen bonds). Of the set of 954 constraints per monomer, 824 NOEs with good quality buildup curves were used in the IRMA and DINOSAUR calculations, the others being introduced as qualitative constraints. From the stereospecific assignment procedure, which resulted in the assignment of 16 β -methylene diastereotopic proton pairs (40%) and of the methyl groups of four valine residues, constraints could be imposed on 21 χ_1 dihedral angles.

In the initial stage, a set of 51 structures was generated with DG and further refined with a combination of REM and RMD using the GROMOS force field⁸⁸ in a parallel refinement protocol. Distance constraints were obtained from the set of 854 NOE buildups via relaxation matrix calculations from the ensemble of structures, except for the initial cycle in which a structure obtained by Breg et al.⁸⁹ was chosen as the model. Methyl group rotation, aromatic ring flips, and internal mobility effects (via order parameters obtained from a free MD run in water) were included in these calculations. Convergence was obtained after three IRMA cycles. The best 16 structures were finally refined with direct NOE constraints following a slow-cooling SA protocol from 600 to 1 K in 1.5 ps followed by REM.⁸⁸ In this final refinement stage, theoretical NOE intensities were directly compared with the experimental data using a simple quadratic restraining potential [$x = 1$, $y = 2$ in equation (20)] with, as weighting factor, an experimental error defined as $w_{ij} = (N + \epsilon A_{ij}^{\text{exp}})^{-2}$.⁵⁰ N corresponds to a noise level and ϵ to a relative error on the experimental intensities. The forces were derived using the simple two-spin approximation for the gradient of the NOE function [equation (23)]. Dynamic assignment was applied to the peaks involving unassigned diastereotopic groups.

A view of the backbone of the 16 best Arc structures at various stages during the refinement (DG/SA, IRMA 1st, 2nd, and 3rd cycles, and DINOSAUR) is presented in Figure 2, which clearly shows the improvement of the structures. The precision of the well-defined region of Arc (residues 8–48) including the β -sheet and the two α -helices increases during the IRMA refinement as confirmed by the rmsd (from the average) shown in Figure 3(a). The rmsd for the backbone atoms decreases from 1.0 Å for the DG/SA structures to 0.50 Å for the structures obtained after the third IRMA cycle. This value increases slightly to 0.55 Å after the direct NOE refinement indicating that the use of direct NOE constraints might introduce more variability in the structures (due to spin diffusion effects there are more ways to fulfill a

Figure 2 View of the Arc repressor structures during the refinement with NMR constraints. The structures corresponding to the 16 best final conformations are shown directly after the DG/SA calculations in the first IRMA cycle, after each IRMA cycle, and after direct NOE refinement with DINOSAUR. The structures were superimposed on C- α , C, N atoms of the well-defined region of Arc (residues 8–48 of each monomer)

Figure 3 (a) All heavy atom and backbone atom rmsd from the average for the well-defined region of the Arc repressor (residues 8–48 of each monomer) calculated for an ensemble of 16 structures as a function of the refinement. The structures were superimposed on backbone atoms of the well-defined core. (b) R factors ($Q^{1/6}$ definition) of the Arc structures as a function of the refinement

NOE constraint than a distance constraint). The R factors ($Q^{1/6}$ definition),⁸⁷ however, show a substantial decrease during the DINOSAUR refinement step as can be seen from Figure 3(b). The final structures satisfy the NMR constraints with no significant deviations from dihedral angle restraints obtained from J coupling data and very low R factors, indicating a very good agreement with the experimental NOE data.

The distribution of the experimental constraints as a function of the residue sequence is plotted in Figure 4, together with the precision (rmsd on C- α and all heavy atoms), the backbone angular order parameters [equation (35)] and the $Q^{1/6}$ factors. A correlation can be noticed between the number of constraints and the precision per residue, but no such relationship can be found for the $Q^{1/6}$ factors which all represent low values (~ 0.05) (for comparison, the $Q^{1/6}$ factors for a linear chain of Arc have values of around 0.55). Regions of high variability are found in the N- and C-terminal parts for which few

Figure 4 Number of constraints, rmsd (from the average) on C- α atoms and on all heavy atoms [the structures were superimposed on C- α ,C,N atoms of the well-defined region of Arc (residues 8–48 of each monomer)], backbone angular order parameters (averages from ϕ and ψ angular order parameters) [equation (35)], and $Q^{1/6}$ factors as a function of the residue sequence for the final Arc structures. Secondary structure elements in Arc are indicated. (The rmsd of the first four residues are off-scale and have values of up to 10 Å)

constraints are available. The structures, which have been deposited in the Brookhaven Protein Data Bank (entry 1ARR), have good stereochemical qualities and present an extensive pattern of hydrogen bonds and a good packing with a very well defined core.

6 CONCLUSION

The use of relaxation matrix calculations for the refinement of protein structures from NMR, as illustrated here for the Arc repressor, should result in a more accurate representation of the solution structure of a biomolecule. In addition, such methods also offer a tool to identify errors or overinterpretation in distance constraints and assess the quality of the NMR structures by a direct comparison of theoretical and experimental data. They should however not be used as single criteria for accuracy, but should be used together with others, such as the

stereochemical quality of the structure. An adequate description of motional effects like internal mobility (e.g. via order parameters, fast methyl group rotation, and aromatic ring flips) or conformational heterogeneity, allows a dynamic description of the structure in solution. A treatment of the experimental NMR data as time- and/or ensemble-averaged restraints should even lead us further toward a more realistic description of solution structures. Additional work is however required in this direction since the motional model is the most controversial point in the use of relaxation matrix calculations. The new developments both in software and hardware should extend the range of such computations to proteins of increasing size and allow the use of more detailed motional models for a better description of solution structure.

1 INTRODUCTION

Interest in selective relaxation experiments was aroused when it emerged that it was possible to interpret experimental selective relaxation parameters in terms of different relaxation contributions. Considering the dipole–dipole interaction between $I = \frac{1}{2}$ nuclei as the dominant relaxation contribution of biomolecules in solution, selective relaxation experiments can be used to calculate both selective ‘cross-relaxation’ rates σ_{ij} and individual, direct self-relaxation rates ρ_i . The observation of specific dipolar connectivities can provide useful information on several aspects of the chemical behavior of biomolecules, especially molecular structures and organization, solution dynamics, and biomolecular interactions.

2 SELECTIVE PULSE EXCITATION

Any selective relaxation experiment is performed with a specific pulse sequence which contains at least one selective excitation period. An ideal selective pulse should have the following features:^{1,2}

1. good frequency selectivity (i.e. uniform excitation of a limited spectral region);
2. short duration (to avoid effects such as relaxation, chemical shift, and coupling evolution during the pulse);
3. uniform phase behavior of the magnetization.

Several approaches, recently reviewed,^{1–3} have been developed, to generate excitation profiles to yield selective perturbation, starting from the pioneering work of Alexander.⁴ The pulse sequences proposed for selective excitation can be regarded as belonging to the following categories:

1. rectangular sequence;
2. DANTE sequence;
3. shaped sequence.

2.1 Rectangular Sequences

Rectangular sequences are single, soft pulses obtained like an ordinary hard pulse but with low-amplitude power of the radiofrequency field and a long pulse duration. Two main disadvantages are the low-frequency selectivity and the long excitation time.⁵

2.2 DANTE Sequence^{6,7}

The DANTE sequence is an ingenious system for selective excitation using high-power pulses. It consists of a sequence of 10–100 short, high-power pulses with a pulse angle $\phi < \pi/2$ and a repetition frequency $1/\tau$. The effect generated on a magnetic moment vector is similar to that of a soft rectangular pulse with a larger selectivity that improves as the number of pulses in the pulse train is increased. With respect to the soft rectangular pulse, the DANTE sequence generates a set of excitation bands at a frequency n/τ (where n is an integer 1, 2, 3, etc.) symmetrical with the transmitter frequency ω_0 .

Important improvements to the original DANTE sequence have increased the frequency selectivity (reducing the effect of side lobes of the excitation function) by pulse-shaping with DANTE⁸ and have enabled selective simultaneous excitation of two frequencies by double-DANTE sequences.⁹

2.3 Shaped Pulses

Selective relaxation experiments require the generation of sharp selective pulses that cannot be obtained from soft rectangular pulses. An almost ideal excitation profile requires smoothing of the side lobes in the frequency domain. This is now achieved by appropriate pulse-shaping procedures, which usually require a pulse-shaping spectrometer device.

Gaussian pulse shaping was one of the first shaping functions to be used.^{5,10,11} Now a number of different shaping functions are available to generate selective soft pulses for any multidimensional relaxation experiment. Tables 1 and 2 (from Kessler et al.)¹ show the main characteristics of the different soft excitation pulses and their ‘recommended’ applications.

3 THE DIPOLAR RELAXATION MECHANISM

In solution the exchange of magnetic energy between excited nuclei and the lattice occurs mainly through dipole–dipole interactions between $I = \frac{1}{2}$ nuclei. The efficiency of energy diffusion from ‘hot’ nuclei (excited) to the ‘cold’ lattice is a function of internuclear distances between spin- $\frac{1}{2}$ nuclei and the modulation of these internuclear vectors by dynamic processes, typical of molecules in solution. The time evolution of the z component magnetization of two spins I and S in a dipolar interaction has the form^{12,13}

$$\frac{d\langle I_z \rangle}{dt} = -\rho_I(\langle I_z \rangle - I_0) - \sigma_{IS}(\langle S_z \rangle - S_0) \quad (1)$$

$$\frac{d\langle S_z \rangle}{dt} = -\rho_S(\langle S_z \rangle - S_0) - \sigma_{SI}(\langle I_z \rangle - I_0) \quad (2)$$

where $\langle I_z \rangle$ and $\langle S_z \rangle$, and S_0 and I_0 are the z components and the equilibrium values of magnetization of spins I and S , ρ_I

2 SELECTIVE RELAXATION TECHNIQUES IN BIOLOGICAL NMR

Table 1 Characteristics of the Soft Excitation Forms

Form of soft excitation	Special hardware requirements ^a	Excitation function (frequency domain)		Offset-dependent phase gradient	Selectivity ^b	Side lobes	Comments
		Absorptive component	Dispersive component				
Hermite	Pulse-shaping device	Gaussian	Yes	Large, linear	Similar	No	
Rectangular DANTE ^c	None	flattened top	Yes	Large, linear	Worse	Yes	Main band and sidebands
	None	sinc	Yes	Large, linear	Worse	Yes	
90° Gaussian	Pulse-shaping device	Gaussian	Yes	Large, linear		No ^d	
Half Gaussian	Pulse-shaping device	Almost Gaussian	Yes	Large, nonlinear	Worse	No	Dispersive component shows low selectivity
Purged half Gaussian	Pulse-shaping device	Almost Gaussian	No	None	Better	No	
90° – α_{sel}	None ^e	sinc ² (near resonance)	No	None	Worse	Yes ^e	Low sensitivity to B_1 inhomogeneity
270° Gaussian	Pulse-shaping device	Almost Gaussian	Yes	Small, linear ^f	Worse	Yes	Slightly higher ^b sensitivity to B_1 inhomogeneity ^b
Pulse shaping by DANTE	None	Any desired function	^g	^g	^g	^g	Main band and sidebands
Tailored excitation	None	Any desired function	^g	^g	^g	^g	^g

^aIn general pulse shaping by DANTE possible for all of the shaped pulses.

^bIn comparison with the Gaussian.

^c‘Rectangular’ without modulation.

^dAfter application of phase correction.

^eDepends on the soft pulse used.

^fOnly in a small area in the center of the excitation band.

^gDepends on the excitation sequence.

Table 2 Recommended Applications of the Different Soft Excitation Forms

Form of soft excitation	Recommended application	Evolution of J and Ω during the pulse
Hermite	In cases where uniform excitation is needed	Yes
Rectangular	Only for experiments with low demand on selectivity	Yes
DANTE	For simultaneous excitation of two resonances; excitation of an off-resonance signal	Yes
DANTE	by a side band	Yes
90° Gaussian	Pulse sequence that requires antiphase magnetization for mixing	Yes
Half Gaussian	Pulse sequence that requires antiphase magnetization for mixing; purging of dispersive component accomplished by mixing sequence ^a	Negligible at the end
Half Gaussian	As above, but experiments with need for explicit purging ^b	Negligible at the end
Purged half Gaussian	Pulse sequence starting with antiphase magnetization for mixing	Negligible at the end
90° – α_{sel}	As for the purged half Gaussian in cases with no high selectivity requirements	Yes
270° Gaussian	^c	Partially refocused
Pulse shaping by DANTE		^c
Tailored	Solvent peak suppression; excitation of arbitrary spectral regions; hole burning	^c

^aE.g. TOCSY or by the phase cycling of 90° pulse before the NOESY mixing.

^bE.g. ROESY.

^cDepends on the excitation sequence.

and ρ_S the direct self-relaxation rates, and $\sigma_{IS} = \sigma_{SI}$ the ‘cross-relaxation’ rates. In this case the relaxation process assumes an exponential decay with a rate constant R_1 , the spin–lattice relaxation rate:

$$R_1^i = \rho_i + \sigma_{ij} \quad (i = I, S), (j = S, I) \quad (3)$$

For multispin interaction, as occurs in complex systems of biomolecules, the ‘nonselective’ spin–lattice relaxation rate R_1^{NS} of an i nucleus interacting with neighboring j nuclei can be described by a modified version of Equation (3):

$$R_1^{\text{NS}} = \sum_{i \neq j} \rho_{ij} + \sum_i \sigma_{ij} + R^* \quad (4)$$

with the approximation of independent pairwise interactions and considering the contribution of nondipolar relaxation processes R^* .

The explicit form of ρ_{ij} and σ_{ij} in the case of intramolecular dipolar interactions are:

$$\rho_{ij} = \frac{1}{10} \frac{\gamma_H^4 \hbar^2}{r_{ij}^6} \left(\frac{3\tau_c}{1 + \omega_H^2 \tau_c^2} + \frac{6\tau_c}{1 + 4\omega_H^2 \tau_c^2} + \tau_c \right) \quad (5)$$

$$\sigma_{ij} = \frac{1}{10} \frac{\gamma_H^4 \hbar^2}{r_{ij}^6} \left(\frac{6\tau_c}{1 + 4\omega_H^2 \tau_c^2} - \tau_c \right) \quad (6)$$

where $\hbar$ is the reduced Planck's constant, γ_H and ω_H are the proton magnetogyric ratio and Larmor frequency respectively, r_{ij} the internuclear distance, and τ_c the effective correlation time which modulates the i - j magnetic interaction.

When the excited i nucleus relaxes with j nuclei at their thermal equilibrium, the 'cross-relaxation' term vanishes¹⁴⁻¹⁶ [as the difference between the second terms of equations (1) and (2) becomes zero] and equation (4) becomes:

$$R_{li}^{SE} = \sum_{i \neq j} \rho_{ij} \quad (7)$$

where R_{li}^{SE} is the selective spin-lattice relaxation rate.

Selective excitation of two (or more) resonances adds a selective cross-relaxation term to equation (7) and the relaxation process is driven by the biselective spin-lattice relaxation rate¹⁷ R_{li}^{BS} :

$$R_{li}^{BS} = \sum_{i \neq j} \rho_{ij} + \sigma_{ij} \quad (8)$$

Proton and ^{13}C nuclei can be regarded as limiting examples of complexity for dipolar relaxation analysis and, in both cases, the possibility of using spin-lattice relaxation rates for conformational investigations is based on the ability to dissect the complex relaxation process of a multispin system.

In principle, internuclear distances can be measured for biomolecules in solution provided that (1) they have a single predominant structure or a limited number of conformers and (2) a single ρ_{ij} or σ_{ij} can be experimentally measured. This can be achieved by selective spin-lattice relaxation techniques and by combining selective relaxation rates and nuclear Overhauser effects (NOEs) as described below.

As shown by equation (4) in nonselective spin-lattice relaxation experiments on proton nuclei, the measured relaxation rate is the sum of many terms related to all the direct and σ_{ij} cross-relaxation contributions. Thus, only limited information on molecular conformation and dynamics can be obtained from nonselective proton relaxation data since several different internuclear distances and correlation times determine the experiment rate. No structural information can be obtained from the conventional ^{13}C selective relaxation of protonated carbon atoms since the one-bond C-H interaction dominates the relaxation process, and conformational analysis by studying the relaxation of quaternary carbons is complicated by the multiplicity of long-range C-H interactions.^{18,19}

The selective excitation of single (or double) protons simplifies the nuclear relaxation pathway and can be performed by a variety of techniques.^{1,2,4,20} If the experimental conditions are such that the selective relaxation process of a nucleus involved in dipole-dipole interactions is described by the above equations, simple and reliable methods of calculation of relaxation parameters from selective relaxation measurements can be used, and structural and/or dynamic information can be obtained.

Although selective relaxation parameters can be efficiently used as tools to investigate conformational properties and biomolecular interactions in small and medium-size molecules, cross-relaxation processes may be profoundly altered under the slow motion conditions ($\omega_0 \tau_c \gg 1$) typical of large biomacromolecules such as proteins, nucleic acids, and polysaccharides. When these dynamic conditions apply, the rate of transfer of spin energy between nuclei becomes much larger than the rate of transfer of energy to the lattice. The process of propagation of the magnetization in the network of dipolar-coupled spins, known as 'spin diffusion',²¹ has the effect of destroying differences in spin-lattice relaxation rates in the molecules so that all tend to the same value.²²⁻²⁴

Analyzing the relaxation process on a short timescale, i.e. using the 'initial rate approximation', it has been possible to simplify the interpretation of the results on the basis of a hypothetical two-spin system, but large problems still remain due to the extensive overlapping resonances typical of biomacromolecular spectra.

Some novel one-dimensional (1D)²⁵⁻²⁷ and two-dimensional (2D)²⁸⁻³⁰ methods have recently eliminated the 'spin diffusion' process by exclusion of selected nuclei from the dipolar-coupled bulk proton network^{29,30} or by removing the interference of all protons other than the selected pair.²⁵⁻²⁷ In the era of 1D, 2D, three-dimensional, and multidimensional NMR these methods can open up a new age for the application of selective relaxation measurement to study large biomacromolecules.

4 GENERAL REMARKS ON SELECTIVE RELAXATION EXPERIMENTS

In order to perform selective relaxation experiments, the use of pulse sequences able to perturb the nuclear spin population is required. Initial relaxation rates can be obtained provided that the experiment is correctly carried out and that theoretical problems do not quench the dipolar relaxation strategy. As the recovery of the longitudinal component of nuclear magnetization very rarely follows a true exponential decay, it is important to analyze under what circumstances these undesired effects can be avoided. Unfortunately the main effects that alter the exponential behavior of the magnetization are intrinsic, as they arise in coupled spin systems and are due to dipole-dipole 'cross-relaxation' effects and scalar coupling.^{31,32}

4.1 Cross-Relaxation Effects

As shown by equations (1) and (2), the recovery of the longitudinal component of the magnetization is usually described by two constant rates ρ and σ , and only under special conditions is this behavior a pure exponential. This is the case

for ^{13}C magnetization measured under conditions of continuous broadband proton decoupling, where proton irradiation sets up and maintains a constant spin population of allowed energy levels such that cross relaxation no longer affects the recovery curve. Similar behavior is expected for selective proton relaxation in cases of weak dipolar coupling or when the effect of cross-relaxation diffusion is truncated using the initial slope approximation. In the latter case the experimental relaxation parameter is calculated by measuring the initial rates in the semi-logarithmic plot of reduced intensity $(I_0 - I_z)/2I_0$ vs. delay times. In more general cases, especially in biological systems, the presence of a network of dipolar-coupled spins induces cross-relaxation contributions that change the pure exponential decay. Nevertheless, at least for small and medium-size biomolecules and for dipolar interactions within a 3.5 distance, the initial rate approximation can be used to interpret the data in terms of two-spin systems and to calculate by numerical simulation the direct self-relaxation rate and the 'cross-relaxation' contributions. A more complex situation occurs when the fast motion conditions $\omega_0^2\tau_c^2 \ll 1$ do not hold, as in large biomolecules. Under these conditions, due to spin diffusion, the initial slope approximation is no longer valid, especially for long-range interactions, and only recently has it been possible to determine by virtue of synchronous nutation experiments^{25–27} the structural properties of proteins from cross-relaxation data obtained by selective relaxation measurements.

4.2 Scalar Coupling

In strongly coupled spin systems, the transition probabilities for the components of a spin multiplet are no longer equal. An important element of symmetry is thus lost, even though the excitation pulse acts equally on all multiplet components. Even for a single two-spin system AB, the zero quantum, single quantum and the double quantum transition probabilities do not assume the classical form,^{31–33} but a mixing term W_{AB} appears. It is this last term W_{AB} that causes different recovery curves for the components of a spin multiplet with a specific deviation from pure exponential magnetization decay.

However the perturbative effect of scalar coupling on the behavior of the magnetization recovery curve can be considered a priori. Moreover the 'classical' relaxation equations are still valid when $\Delta\omega/J > 10$, where $\Delta\omega$ is the difference in chemical shift between two spins and J is their scalar coupling constant. This is a general condition met in studying biological systems. Again the synchronous nutation experiment²⁷ has simplified the problem of correctly calculating the relaxation parameter in the presence of strong scalar coupling, by removing all scalar interactions between spins that are irradiated (active) and at Boltzmann equilibrium (passive). Although the effect of strong scalar coupling between irradiated (active) spins can still affect the recovery curve, its contribution can be taken into account by simple numerical analysis.

5 APPLICATION OF SELECTIVE RELAXATION TECHNIQUES IN BIOLOGICAL SYSTEMS

Many papers have fairly recently been published^{25,34–38} proposing the use of selective relaxation experiments to investigate biological systems. For simplicity, proton homonuclear

and heteronuclear interactions and their field of application will be treated separately.

5.1 Homonuclear Selective Relaxation Experiments

In ^1H homonuclear spin systems, the nonselective inversion recovery, $180^\circ\text{-}\tau\text{-}90^\circ$ pulse sequence gives partially relaxed spectra in which it is possible to follow the recovery of the Boltzmann equilibrium for each resonance by individual constant rates (R_1^{NS}) which are the sum of two contributions: the direct and the cross-relaxation terms [as described by equation (4)]. It has been shown by Freeman et al.¹⁴ that cross relaxation may be negligible provided that the 180° pulse selectively excites single-proton resonances. In particular, if the initial relaxation is monitored after selective population inversion of proton i , i.e., short delays are used between the selective and the nonselective observing 90° pulse, the initial recovery rate of the magnetization (R_{1i}^{SE}) is described by equation (7). At longer delay times, cross relaxation becomes significant, as can be observed from the intensity changes of the resonances of protons dipolarly coupled to the excited proton. It follows that selective excitation techniques can be used to achieve a simplification of the proton relaxation process and to calculate the selective dipolar relaxation contribution to the observed spin–lattice relaxation rate.

The initial selective relaxation rate R_{1i}^{SE} is an important parameter which can be used to obtain information on: (1) relaxation mechanisms, (2) molecular dynamics, and (3) molecular conformations.

1. In molecular systems which satisfy the extreme narrowing condition $(\omega_0\tau_c)^2 \ll 1$, for proton i , the ratio between the nonselective relaxation, R_1^{NS} , and R_{1i}^{SE} is diagnostic of the efficiency of the dipole–dipole relaxation mechanism, since this ratio, F_i , is equal to 1.5 for a relaxation pathway completely dominated by the i – j proton dipolar interactions.³⁹
2. As shown in Figure 1, F_i also depends on $\omega_0\tau_c$ and, hence, for rigid isotropically reorienting molecules, motions can be quantified from the latter parameter.³⁹
3. The combined use of R_{1i}^{SE} and homonuclear Overhauser effects, NOEs, yields an absolute evaluation of σ_{ij} rates since, neglecting cross-polarization effects, the following relationship holds⁴⁰

$$\text{NOE} = \sigma_{ij}/R_i(\text{SE}) \quad (9)$$

where NOE is the Overhauser effect on proton i upon selective excitation of proton j .

The calculation of the cross-relaxation rate relative to a single i – j dipolar interaction is also possible by the simultaneous double excitation of protons i and j . If selectivity in the double excitation can technically be achieved, the relaxation process is driven by the biselective relaxation rate, R_{1i}^{BS} , as shown by equation (8).

It should be noted that the initial conditions for the evaluation of R_{1i}^{BS} are critically important because the peak intensities observed in the partially relaxed spectra are determined by the relaxation process and the time-dependent i – j NOE.^{31,41}

Homonuclear selective relaxation experiments are widely used to investigate different properties of biological systems. The most interesting approaches are related to the analysis of:

Figure 1 (a) Dependence of $F = R_i(\text{NS})/R_i(i)$ versus $\log \omega_0 \tau_c$. (b) Behavior of $RSE/1$ (1), $RNS/1$ (2), and σ_{ij} (3) for a two-spin system under different dynamic conditions; (1), (2), and (3) are readily generalized for proton i , involved in multiple interactions with several protons, $i \neq j$. (Reproduced by permission of Academic Press from N. Niccolai et al.³⁹)

1. conformational and dynamic properties of biomolecules in solution;
2. the interaction process between ligand and biological receptors;
3. the behavior of water in the presence of large, organized biological systems.

5.1.1 Conformational and Dynamic Properties of Biomolecules in Solution

The network of intramolecular dipolar connectivities in small to medium-size biomolecules can be easily evaluated by selective relaxation experiments. The most suitable approach consists first of calculating the cross-relaxation rates between selective proton pairs as the difference between selective and bisselective relaxation experiments:

$$\sigma_{ij} = R_{1i}^{\text{BS}} - R_{1i}^{\text{SE}} \quad (10)$$

$$\sigma_{ji} = R_{1j}^{\text{BS}} - R_{1j}^{\text{SE}} \quad (11)$$

in which $\sigma_{ij} = \sigma_{ji}$ are the cross-relaxation values obtained from analysis of the relaxation properties of the i and j

nuclei, respectively. Selective homonuclear NOE experiments can also be used to evaluate σ_{ij} . Figure 2 shows an example of proton-selective and bisselective experiments used for calculating σ_{ij} . The effect of the additional cross-relaxation contribution to the magnetization recovery process in the bisselective experiment, is evident.

As shown by equation (6) and Figure 3, σ_{ij} contains both structural (r_{ij}) and dynamic (τ_c) information.⁴² Constant calibration distances are required for the calculation of the effective correlation time τ_c . This is easily achieved by considering independent conformational distances as geminal interactions of CH_2 groups, *ortho* protons of aromatic residues, etc.

As shown in Figure 1, $F_1 = R_{1i}^{\text{NS}}/R_{1i}^{\text{SE}}$ can be used as a probe for molecular motion assuming as dominant the intramolecular dipolar mechanism. Carbon-13 relaxation measurements (see next section) obtained under broadband proton decoupling can also be used to map the distribution of motions along a biomolecule or to verify isotropic tumbling in systems with restricted internal flexibility. A detailed description of the modulation of the dipole-dipole interaction allows selected interproton distances, from which the solution conformation can be derived, to be calculated with confidence. From the first papers^{39,43,44} in which this approach was proposed, nearly every class of biological molecule was investigated: amino acids,^{43,45} peptides,⁴² carbohydrates,⁴⁶ oligosaccharides,^{47,48} drugs,^{49,50} natural products,^{37,51,52} etc.

Recently when the 2D approach for studying dipolar networks seemed to diminish the importance of these selective relaxation studies, a new selective experiment was proposed which enabled large macromolecules such as proteins to be investigated²⁵ (Figure 4). According to this new approach, one or two proton resonances are simultaneously excited by an amplitude modulated radiofrequency field which forces the magnetization vectors to undergo simultaneous motion defined as ‘synchronous nutation’.^{25–27} Time-dependent analysis under different initial conditions allows calculation of the direct self-relaxation rate or the ‘cross-relaxation’ term. In the ‘synchronous nutation’ experiment, the neighboring spins do not affect the magnetization behavior of the selectively isolated spin system even in the presence of the spin diffusion typical of slow molecular tumbling $\omega_0 \tau_c \gg 1$ conditions. Conformational studies (through selected-pair distance determination) by selective relaxation measurements in large biomacromolecules appear to be a valid alternative to the classical approach based on 2D analysis of dipolar-coupled spin systems.

5.1.2 Intermolecular Interaction: Ligand–Macromolecular Receptor

Ligand–macromolecule interactions can be detected by selective relaxation measurements. The formation of intermolecular adducts affects nonselective and selective spin–lattice relaxation rates to different extents, assuming that fast chemical exchange occurs between the bound and free environments with respect to both the chemical shift difference and the proton relaxation rate.⁵³

If only two environments are considered, the relaxation parameters are expressed by:

$$R_{\text{obs}}^A = \chi_f R_{1f}^A + \chi_b R_{1b}^A \quad (12)$$

Figure 2 Proton-selective and biselective partially relaxed spectra obtained by selective inversion of the magnetization of H-1' (a) and of both H-1'–H-3 (b) protons of a 0.15 mol dm⁻³ gentiobiose octaacetate solution in dimethyl sulfoxide-*d*₆. *T* = 300 K. The delay values between the selective and nonselective pulses were: 5, 10, 20, 40, 80, 100, 200, 400, 600, 800, 1000, 2000, and 10 000 ms

Figure 3 Isosigma contours for $\log \omega_0 \tau_c$ vs. interproton distances calculated from equation 6; the selected σ values are expressed in s⁻¹. (Reproduced by permission of Elsevier from N. Niccolai, L. Pogliani, C. Rossi, P. Corti, and W. A. Gibbons, *Biophys. Chem.*, 1984, **20**, 217)

where χ_f and χ_b are the ligand fractions in the free and bound environments. Since $\chi_f + \chi_b = 1$ and taking $\chi_b \ll 1$, equation (12) becomes:

$$R_{\text{obs}}^A = R_{\text{lf}}^A + \chi_b R_{\text{lb}}^A \quad (13)$$

Figure 4 Selective inversion–recovery measurements of the aromatic protons H^δ and H^ε of the tyrosine (Tyr) residue in bovine pancreatic trypsin inhibitor dissolved in ²H₂O at 327 K. The inset shows the aromatic region (between 8.2 and 5.8 ppm) of the 1D spectrum (eight scans); the arrows indicate the shifts of H^ε at 6.30 ppm and of H^δ at 7.20 ppm. Lower part: normal inversion–recovery measurement of H^ε in Tyr²³ using selective pulses and direct observation of H^ε. Upper part: inversion–recovery of H^δ using selective pulses and Hartmann–Hahn transfer from H^δ to H^ε. (Reproduced by permission of the American Chemical Society from B. Boulat, R. Konrat, I. Burghardt, and G. Bodenhausen, *J. Am. Chem. Soc.*, 1992, **114**, 5412)

where A = SE or NS. From equation (13) it emerges that only experimental parameters broadly affected by the ligand–macromolecular interaction make the second term of equation (13) significant. Binding of a ligand to a macromolecular receptor slows down its reorientation motion from $\omega_0 \tau_c \ll 1$ to $\omega_0 \tau_c \gg 1$. In diamagnetic systems where the dipole–dipole interaction is the dominant relaxation mechanism, entering into the slow-motion region does not significantly alter the nonselective spin–lattice relaxation rates [equation (4)]. On the contrary, the selective relaxation of the bound ligand can be expected to be quite different from that

Figure 5 $R_{1}^{NS}/1$ and $R_{1}^{SE}/1$ of a proton pair versus $\omega_0\tau_c$ assuming a constant r_{i-j} distance (1.77 Å) for the $i-j$ dipolar interaction. The equilibrium between the ligand molecules in the bulk ($\omega_0\tau_c \ll 1$) and DNA-bonded ($\omega_0\tau_c \gg 1$) is also shown. (Reproduced by permission of Elsevier from C. Rossi, A. Donati, and M. R. Sansoni, *Chem. Phys. Lett.*, 1992, **189**, 278)

of the free ligand in solution as shown in Figure 5 for a ligand–DNA interaction.³⁶

Since the study of biomolecular interactions by selective relaxation measurement is based on a slowing of ligand molecular motion, the effect of the macromolecular receptor on the viscosity of the system must be considered. Temperature-dependent analysis of R_{1}^{NS} can address this point. In fact as seen in Figure 5, fast-motion ($\omega_0\tau_c \ll 1$) and slow-motion ($\omega_0\tau_c \gg 1$) conditions show opposite slopes, so hypothetical, drastic changes in viscosity due to the receptor site can be monitored simply by following R_{1}^{NS} dependence on temperature.^{36,54} This method is very powerful since it has a wide range of applications in biological systems. As the information is gained from selective relaxation rates of the ligand, ill-defined receptors in biological samples⁵⁵ such as blood whole cells etc. can be investigated and receptor purification followed.

A wide range of ligand–biomacromolecule interactions have been investigated by selective spin–lattice relaxation rate analysis;⁵⁶ these include enzyme–substrate,⁵³ drug–membrane interactions,⁵⁷ and recently ligand–DNA,³⁶ for the purpose of identifying potential mutagens and toxic compounds. This approach can also be used to calculate the association constant for the interaction processes.⁵⁸

5.1.3 Water Selective Relaxation in Large Organized Biological Systems

Water proton relaxation rates have been found to correlate with the physiological and pathological state of the cell as well as to the conformational state of cell constituents.^{59–61} Experimental evidence that water selective relaxation is faster than nonselective water relaxation rates in protein solutions and cell suspensions has focused attention on the relaxation mechanism of water protons in large organized

systems.^{38,62–65} The water spin–lattice relaxation (R_{1W}) may be described as the sum of two contributions:⁶⁶

$$R_{1W} = R_{1A} + R_{1B} \quad (14)$$

where R_{1A} and R_{1B} are the intra- and inter-molecular relaxation rates. The intramolecular term is due to:

$$R_{1B} = R_{1WW} + R_{1WM} \quad (15)$$

R_{1WW} is the dipolar contribution due to intramolecular water–water interactions and R_{1WM} that arising from water–macromolecule (or cell constituent) interactions.³¹ The latter interaction can yield direct ρ_{WM} and cross-relaxation σ_{WM} contributions from simultaneous water and macromolecule proton excitation:

$$R_{1WM} = \sum \rho_{WM} + \sum \sigma_{WM} \quad (16)$$

If the water relaxation rate is measured in the selective mode, only a small fraction of the macromolecule protons are excited and the σ_{WM} term disappears. It follows that in the presence of large biological surfaces:⁶⁵

$$R_{1W}^{NS} - R_{1W}^{SE} = \sum \sigma_{WM} \quad (17)$$

where R_{1A} and R_{1WW} are constants in nonselective and selective experiments respectively. Experimental evidence obtained for protein solutions and cell culture suspensions shows that the difference between nonselective and selective relaxation rates [equation (17)] are not only due to the dynamic change in the solvent molecules but also to dipolar intermolecular connectivities between the solvent and the surface of hydrophilic regions of macromolecules. This suggests that it would be useful to use the complete set of relaxation parameters, such as R_{1W}^{NS} , R_{1W}^{SE} , and σ_{WM} to investigate the physiological and pathological state of cells or to study drug–cell and virus–cell interactions;⁶⁷ R_{1W}^{NS} to probe essentially dynamic features of the heterogeneous systems, and R_{1W}^{SE} and σ_{WM} to study the water–macromolecule magnetic energy transfer process, which is intimately linked to the solvent exposed interface structure assumed by the biological material.

5.2 Heteronuclear Selective Relaxation Experiments

Our discussion will be limited to the ^{13}C nucleus, due to its importance for verifying dynamic and structural information on biological systems.

In spite of the low sensitivity of heteronuclei with respect to protons, several advantages exist. Carbon-13 signals are spread over a large chemical shift range (over 300 ppm). The carbon resonances can be treated as single resonances removing proton scalar coupling by a broadband decoupling pulse. Under these conditions the carbon relaxations can be regarded as pure exponential, determined by a single contribution: the direct self-relaxation term. Furthermore, relaxation contributions due to intermolecular interactions are seldom significant (as the carbons are shielded by the proton surface) and, in natural abundance experiments, homonuclear ^{13}C – ^{13}C dipolar interactions are rare due to ^{13}C isotopic dilution. These properties make carbon relaxation a suitable parameter for investigating solution properties of biomolecules.

5.2.1 ^{13}C Selective Relaxation

In conventional ^{13}C relaxation experiments (obtained by broadband proton decoupling), cross relaxation between carbon nuclei is ignored and the measurement gives the selective, direct carbon spin–lattice relaxation rate:

$$R_{1C}^{\text{SE}} = \sum \frac{1}{10} \frac{\hbar^2 \gamma_H^2 \gamma_C^2}{r_i^6} \left[\frac{3\tau_c}{1 + \omega_C^2 \tau_c^2} + \frac{6\tau_c}{1 + (\omega_H + \omega_C)^2 \tau_c^2} + \frac{\tau_c}{1 + (\omega_H - \omega_C)^2 \tau_c^2} \right] \quad (18)$$

R_{1C}^{SE} of protonated carbons are dominated by the dipolar interaction between bonded proton–carbon nuclei.^{17,18} In this case the internuclear proton–carbon distance can be assumed to be constant and the effective correlation time calculated. In flexible molecules, a mapping of dynamic properties may be obtained from the R_{1C}^{SE} of different carbons. If continuous broadband proton decoupling is replaced by a selective 180° proton pulse, applied to the i nucleus, with the first 180° carbon pulse the initial rate of the longitudinal magnetization of carbon is:^{68–70}

$$R_{1C}^{\text{BS}} = R_{1C}^{\text{SE}} + \xi \sigma_{\text{CH}_i} \quad (19)$$

where R_{1C}^{BS} is the biselective carbon relaxation rate $\xi = \gamma_H/\gamma_C$ and σ_{CH} the single proton–carbon ‘cross-relaxation’ term. When the selective 180° proton pulse is replaced by a proton perturbation which can invert the spin equilibrium of the entire proton population, the carbon relaxation is described by:^{69–71}

$$R_{1C}^{\text{NS}} = R_{1C}^{\text{SE}} + \xi \sum \sigma_{\text{CH}_i} \quad (20)$$

The following dynamic and structural information is obtained by comparing R_{1C}^{SE} , R_{1C}^{BS} , and R_{1C}^{NS} measurements.

5.2.1.1 Dynamic analysis. The $R_{1C}^{\text{NS}}/R_{1C}^{\text{SE}}$ ratio takes a value in the range 2.99–1, depending on the molecular motion. In this way the value of the $R_{1C}^{\text{NS}}/R_{1C}^{\text{SE}}$ ratio allows the correlation times for each molecular moiety to be determined (or at least the limit value of τ_c). The $R_{1C}^{\text{NS}}/R_{1C}^{\text{SE}}$ ratio in particular is a very useful parameter for evaluating the effective correlation time of nonprotonated carbon atoms.

5.2.1.2 Structural analysis. The difference between R_{1C}^{BS} and R_{1C}^{SE} gives the cross relaxation term $\sigma_{\text{C}_i\text{H}_A}$ for each ^1H – ^{13}C magnetic interaction which contains distance information. This method has been demonstrated with different natural products, giving reliable results.^{69–71}

5.2.2 Selective Proton–Carbon NOEs

Several authors have shown that selective proton–carbon NOEs, (^1H) ^{13}C -NOE, can be generated.^{72–74} When a selective pulse is used to saturate a single proton then ‘cross relaxation’ between the irradiated proton and the carbon microenvironment occurs. The (^1H) ^{13}C -NOE is described by:^{75,76}

$$(^1\text{H}_A)^{13}\text{C}_i - \text{NOE} = \frac{\sigma_{\text{C}_i\text{H}_A}}{R_{1C}^{\text{SE}} + R_{1C}^*} \quad (21)$$

Figure 6 Carbon-13 spectra of 0.5 mol dm^{−3} rifamycin in CDCl₃ recorded on a Varian XL-200 spectrometer at 296 K: (a) ^{13}C spectrum after irradiation of the phenolic hydroxyl proton; (b) as (a) but with the decoupler set ‘off-resonance’. (c) Difference spectrum (b)–(a). The presaturation selective pulse on the phenolic hydroxyl proton had a 10 s duration and 0.5 W power. During the acquisition of the FIDs the decoupler was on with a power of 4 W in the broadband mode. The structure of rifamycin S is shown. (Reproduced by permission of the American Chemical Society from N. Niccolai et al.⁷⁵)

where $\sigma_{\text{C}_i\text{H}_A}$ is the selective ‘cross relaxation’, R_{1C}^{SE} the selective carbon relaxation rate, and R_{1C}^* the relaxation contribution due to nondipolar interactions [in paramagnetic systems this term often quenches the (^1H) ^{13}C -NOE]. Thus by combining selective NOEs with carbon relaxation rates, specific distance calculations can be obtained.

Although care must be taken in dealing with large macromolecules when magnetization diffusion occurs between spins, this method has been usefully applied to investigate the conformation of biological molecules such as antibiotics, peptides, natural components,^{77–79} etc. Figure 6 illustrates the capacity of (^1H) ^{13}C - NOE to discriminate the carbon microenvironment by selective proton perturbation.⁷⁵

1 INTRODUCTION TO SUPERCRITICAL FLUIDS

While the existence of the supercritical ‘phase’ has been known for over 150 years it has been only in the last 20 years that the value of supercritical fluids (SCFs) as a medium for extraction, cleaning and synthesis has been recognized. It is now clear that SCF processes are often constrained to very narrow regions of economic feasibility due to the phase behavior of the solute-solvent system. As a result, there needs to be very tight controls over any industrial process employing SCFs. If the process parameters must be more exact, then so does the information required to generate the design parameters, which includes experimental measurements, theories, and the correlations that result in predictability in a given system. In an effort to expand the current understanding of SCFs and their applications, intensive studies are ongoing using nuclear magnetic resonance (NMR). In an effort to further explain the physical chemistry inherent to possible applications of SCFs, a brief introduction is given to this odd and often ignored ‘phase’ of substances. Following that is an introduction to NMR as it pertains to the study of SCF applications.

2 SUPERCRITICAL FLUIDS

2.1 General Properties

The supercritical state is defined by the critical pressure (P_c) and critical temperature (T_c). One of the most common phenomenological definitions describes critical pressure as the pressure above which, regardless of the applied temperature, a liquid cannot be made to boil. In a similar way, the critical temperature can be thought of as the temperature above which, regardless of the applied pressure, a gas cannot be converted into a liquid. Hence, above the critical point there is no longer a phase boundary between the liquid and the vapor. A liquid/vapor phase boundary represents a coexistence line so that material crossing it requires the expenditure of the latent heat of vaporization.

The concept of the supercritical state can be illustrated by a physical example. Consider a closed container of constant

volume. Inside the container we start with some amount of pure liquid. The space above this pure liquid will be filled with pure vapor at the liquid’s equilibrium vapor pressure. Now assume that we begin to heat up this container slowly and uniformly. The density of the liquid will begin to decrease through normal thermal expansion. Meanwhile, the density of the vapor phase begins to increase since more molecules are leaving the liquid to enter the vapor phase. Continued heating results in a further decrease of the liquid density and an increase in the vapor density. Eventually, at some temperature, T_c (and resulting, uniform pressure, P_c), the density of the liquid and vapor phases reach the same value, and the vapor and liquid ‘phases’ have identical compositions and identical densities.

Is this supercritical fluid phase to be considered a liquid or a gas? The answer is that a supercritical fluid reflects properties of both. Table 1 shows relative values of the density, diffusion coefficient, and viscosity for a typical liquid, gas, and supercritical fluid. These values indicate the mass transport properties (i.e., diffusivity) are similar to a gas, while the mechanical properties (viscosity and density) are similar to those of a liquid. This unique combination of properties makes supercritical fluids attractive for use as solvents. The high diffusivity and low viscosity allows the fluid to penetrate easily into matrices which are in the form of loose powders, compacted powders, or even fully cemented pre-forms. Further, the ability of a solvent to dissolve other liquids is, to a first approximation, related to the density of the solvent. The relatively high density of supercritical fluids, relative to gases, increases the useful levels of solubility that may be attained.

2.2 Supercritical CO₂

As a result of the law of corresponding states the physical properties of supercritical CO₂ apply to all fluids in the supercritical state. The critical values of temperature and pressure are unique for each gas/liquid and are determined by the type of intermolecular interactions occurring between

Table 1 Comparison of physico-chemical properties of a typical organic fluid in the liquid, gas, and supercritical fluid state

	Liquid	Supercritical fluid	Gas
Density (g cm ⁻³)	1	0.1–1	10 ⁻³
Viscosity (Pa·s)	10 ⁻³	10 ⁻⁴ –10 ⁻⁵	10 ⁻⁵
Diffusivity (cm ² s ⁻¹)	10 ⁻⁵	10 ⁻³	10 ⁻¹

Table 2 Critical temperature, T_c , and Pressure, P_c , for some common fluids

Fluid	T_c (°C)	P_c (psi)
Neon, Ne	–229	400
Nitrogen, N ₂	–147	492
Argon, Ar	–122	706
Xenon, Xe	17	858
Carbon dioxide, CO ₂	31	1072
Sulfur hexafluoride, SF ₆	46	545
Propane, C ₃ H ₈	97	617
Ammonia, NH ₃	133	1654
Water, H ₂ O	374	3209

the individual molecules. Table 2 gives the critical temperature and pressure of some common fluids. For example, the critical temperature and pressure required to transform water (H_2O) into a supercritical fluid are 374°C and 218 atmospheres. These values are much higher than those for CO_2 because the water molecules exert an attractive force on each other, making the solid and liquid phases particularly stable. CO_2 molecules, on the other hand, have much weaker intermolecular attractive forces. It is important to note that, in the SCF region, attractive forces between molecules are minimized.

In the solid form CO_2 has a high density and a very high viscosity. Similarly, the liquid has a high density and a reasonably high viscosity, and the gas has a low density and low viscosity. Conversely, the supercritical fluid phase has a high density but a relatively low viscosity. The density of supercritical CO_2 can vary over a wide range from gas values, around 0.1 g cm^{-3} , to liquid values of about 2.0 g cm^{-3} . In other words, the density of supercritical CO_2 can be changed by over 2000% simply by varying the temperature and pressure within the supercritical region. A supercritical fluid is by definition both liquid and gas-like, and hence it is compressible. Thus, relatively small changes in temperature and/or pressure can significantly affect the density, as seen in Figure 1.

As the density of the CO_2 becomes more liquid-like, so do the solvent properties of the fluid. To a first approximation, the ability of a supercritical fluid to dissolve other fluids can be related to its density in the supercritical region. When operating in the supercritical region, therefore, both temperature and pressure can be used to vary the density, and therefore, the dissolving power of the fluid. It is this ability to alter the solvent power that makes supercritical CO_2 such an attractive solvent. To make the potential for SCFs even more promising, small additions of other components, called co-solvents or entrainers, often modify the observed phase

equilibria dramatically. Again this special property affords the chemist the opportunity to *tailor* solvents to achieve a variety of goals, either in separations or reactions.

The viscosity of carbon dioxide is observed to change rapidly in the critical region, as is the case also for diffusivity. Even at high pressures of 300–400 atm it is still only about 0.09 centipoise, an order of magnitude below typical organic solvents. Because of these density and viscosity properties, supercritical CO_2 possesses certain other characteristics, which enhance its attractiveness as a solvent. In addition to possessing liquid-like densities over much of the temperature and pressure range of interest to industry, it exhibits the gas-like property of diffusivity with a zero value for the surface tension. These features alter the transport to allow for easy penetration of SCFs into nano-dimensional spaces.

The self-diffusion coefficient for carbon dioxide (which is approximately the same for similar sized molecules diffusing through carbon dioxide) is about one to two orders of magnitude higher than the diffusivities of comparable solutes in typical organic liquids.

2.3 NMR of Supercritical Fluids

The interactions of a nuclear moment with other nuclei and the electrons surrounding it provide a very sensitive site specific probe into the structure and dynamics in the solid, liquid, and gas phase. This work will concern itself with NMR in the supercritical fluid state of carbon dioxide. As mentioned above, these states exhibit properties of both the liquid and the gas phases. Thus, techniques and theory from work in both phases combine in these unique applications. Thorough reviews have been published on the unique information which can be obtained in the gas phase.^{1,2} Other reviews have been published on experimental techniques and applications of high pressure NMR.^{3,4} These reviews were published on or before

Figure 1 Pressure–temperature–density surface of pure CO_2

1991. We will discuss primarily studies published later, with information as it relates specifically to NMR determination of the dynamics and structure in the SCF state.

Although the application of high pressure NMR to simple fluids leads to some interesting additional complications, the information gained from the technique more than justifies its use. The pressure axis provides an additional dimension to the experimental matrix. For a liquid it is commonly known that temperature changes at constant pressure will effect the molecular motion via kinetic energy and molecular average volume collisional arguments. One can separate the effects of density and temperature on the molecular motion only if both the temperature and pressure are controlled variables in the NMR experiment. Increased pressure also allows for the experimental range to expand well above the normal boiling point and into the compressible supercritical fluid regime. Some examples of the usefulness of high pressure NMR will be given.

2.4 Introduction to the Basics of High-pressure NMR

The motions of molecules in liquids is accessible only through a large number of various models that depend upon phenomenological parameters such as the coefficient of rotational diffusion, the frequency of collisions, the time between jumps, etc. Three such theories: the random walk theory of Torrey,⁵ the rotational diffusion theory of Abragam,⁶ and the rotational Brownian motion of McConnell⁷ form the basis upon which most NMR relaxation models in liquids are based. Other methods of studying molecular motion (optical, dielectric, neutron scattering, etc.) can in principal give additional detailed information. However, as a consequence of the many-particle effects present in these methods, the interpretation of the experimental results for liquids is often ambiguous. In NMR, the weak coupling of the spin system with the lattice allows one to focus better on isolated molecular motions to describe relaxation in liquids.⁸ Information on the rotational motion of molecules in liquids of low viscosity, given by NMR, is obtained in the form of the integrals of the time correlation functions, i.e., the correlation times. This section will discuss the effects of dense gas and supercritical fluid states on the correlation times, and what this means to the NMR spectroscopist.

2.5 The Origin of Nuclear Spin Relaxation

Direct time dependant interactions have been shown to cause spin relaxation. However any static interaction can simply be treated as part of the normal spin Hamiltonian, altering the positions and intensities of the spectral lines. For example, a nuclear spin may experience a local magnetic field from the spins of other nuclei moving in its vicinity, from an unpaired electron, or from a variety of other mechanisms, such as the spin-rotation interaction in which the rotation of the molecular electrons generates a magnetic field at the nucleus. In general, rotational and diffusional motions are important sources of relaxation in fluids. Some mechanisms that make contributions to spin-lattice relaxation will be discussed.

2.5.1 Nuclear Spin Relaxation Mechanisms

There are a number of processes that provide the basis for nuclear spin relaxation. These include the nuclear magnetic

dipole-dipole interactions (DD), the spin-rotation interactions (SR), the quadrupolar interactions (Q), and the chemical shift interactions, (CSA). The overall relaxation rate can be expressed as a sum of contributions from each mechanism.

2.5.2 Dipole-Dipole Interaction

The magnetic nuclei in molecules provide magnetic dipole fields that are proportional to the magnetic moments of the nuclei. These fields fluctuate in magnitude and direction as the molecule tumbles through space. When these random oscillating fields have magnetic field components at the Larmour frequency, the nuclear spin relaxes. This interaction depends upon the correlation time of the tumbling molecule as well as the distance between the interacting nuclei. The dipole interactions can be divided into intramolecular and intermolecular interactions. For both of these types of interactions there is a homo, and hetero-nuclear sub-interaction. These are reflected in the following equations

$$\begin{aligned} \text{For intra-homo: } \frac{1}{T_1^{\text{DD}}} &= \frac{3\gamma_A^4\hbar^2\tau_c}{2r^6} \\ \text{For intra-hetero: } \frac{1}{T_1^{\text{DD}}} &= \frac{\gamma_A^2\gamma_X^2\hbar^2\tau_c}{r^6} \\ \text{For inter-hetero: } \frac{1}{T_1^{\text{DD}}} &= \frac{2N_s\gamma_A^2\gamma_X^2\hbar^2}{Da} \end{aligned} \quad (1)$$

where r is the distance between the interacting nuclei, D is a mutual translational self-diffusion coefficient for the molecules containing A and X , and a is the distance of closest approach between A and X . τ_c is a rotational diffusion correlation time for molecular tumbling. This corresponds to the average time it takes for a molecule to rotate through one radian.

2.5.3 The Spin-Rotation (SR) Interaction

Spin-rotation relaxation of the nuclear magnetization in molecules is due to the intramolecular coupling of the individual nuclear spins to the molecular angular momentum. A fluctuating local magnetic field, which relaxes the nuclear spins, is the result of the collisional reorientation of the molecular rotational angular momentum. For linear molecules such as CO_2 , the spin-rotation contribution to the total spin-lattice relaxation can be expressed as

$$\frac{1}{T_1^{\text{SR}}} = \frac{4C_{\perp}^2 I k T \tau_j}{3\hbar^2} \quad (2)$$

$C_{\perp}$ is the spin-rotation constant and I is the moment of inertia. For a spherical top molecule, the relaxation rate has the form

$$\frac{1}{T_1^{\text{SR}}} = \frac{2C_{\text{eff}}^2 I k T \tau_j}{\hbar^2} \quad (3)$$

C_{eff} is the effective spin-rotation tensor. The τ_j is the correlation time for angular momentum transfer and therefore is closely related to the average time between collisions. The higher the temperature the faster the molecule reorients in accordance with the kT term. The result is that the spin-rotation contribution to the total spin-lattice relaxation

increases with temperature. This is quite the opposite in all other mechanisms examined in this work.

2.5.4 Quadrupolar Relaxation

Quadrupolar occurs when the nuclear electric quadrupole moment, interacts with electric field gradients to provide a very efficient nuclear relaxation process. The equation for these interactions is similar in form to that of the dipole interaction. The electric quadrupolar interaction between spin I and an electric field gradient can be written in the form given in equation (4).

$$\frac{1}{T_1^Q} = \frac{3\pi^2(2I+3)\chi^2\tau_c}{10[I^2(2I-1)]} \quad (4)$$

where χ is known as the nuclear quadrupolar coupling constant and is in units of frequency. The τ_c here is the rotational diffusion correlation time as it appeared in the dipolar equation. Because of its relative efficiency the quadrupolar interaction nearly dominates when quadrupolar nuclei are present.

2.5.5 Chemical Shift Anisotropy

Anisotropic shielding at the nucleus changes with the orientation of the molecule in a static field. Therefore the molecular tumbling modulates the local magnetic field resulting in relaxation. The spin-lattice relaxation rate due to this interaction is proportional to the square of the magnetic field:

$$\frac{1}{T_1^{\text{CSA}}} = \frac{2}{15}\gamma_A^2 B^2 \Delta \sigma^2 \tau_c \quad (5)$$

where Δ is the chemical shielding anisotropy of the nucleus and τ_c has the same meaning as before.

The spin-lattice relaxation can be measured and contributions from each of the mechanisms decoupled to yield dynamic and structural information pertaining to the species of interest. Each of the following sections will contain specific observation techniques and theoretical treatments used to provide insight into the often strange and unpredictable world of supercritical fluids.

Extensive studies have been performed on nuclear magnetic spin lattice relaxation and its dependence on molecular structure and dynamics. This is the subject of several review articles.^{9–12} Decoupling techniques are often used to enhance the signal and to simplify the resulting spectrum. Such decoupling studies also yield the nuclear Overhauser enhancement (NOE), which allows the unique separation of the dipolar interaction from other relaxation interactions. However, decoupling also eliminates multiplet splittings from scalar couplings, thereby preventing direct measurement of some of the spectral features that are required to completely describe the relaxation of coupled nuclear spin systems.

Spin-coherent double-resonance experiments, which avoid this loss of information, and a general numerical method for analyzing the data obtained in relaxation studies of this type may be used.^{13,14} Relaxation processes, described by a system of coupled linear differential equations, determine a variety of time-independent relaxation parameters that contain information on the molecular structure, and dynamic features of the motion. The relaxation parameters in the equations of

motion can then be extracted from the experimental data using standard least squares methods.^{13,14}

For polyatomic gases, nuclear spin relaxation proceeds primarily from the collisional modulation of the molecular rotational angular momentum coupled to the angular momentum of the nuclear spins. Reorientations of molecular angular momentum by collision then give rise to fluctuating internal magnetic fields, that effect the nuclear spins through intramolecular spin-rotation couplings. In addition to the spin-rotation mechanism molecular motional modulation of the chemical shift anisotropy, dipole-dipole and quadrupolar couplings also affect the relaxation rates.

In low-viscosity liquids and gases, spin-lattice relaxation may be treated as a temporal modulation associated with the thermal reorientation of the molecule. The study of spin lattice relaxation contributes to an understanding of molecular dynamics.¹⁵ In dilute gaseous samples of small molecules where the interactions mediating spin relaxation are primarily intermolecular,^{16,17} and the various interaction parameters are known accurately,^{18–21} the study of relaxation reveals features of collisional processes responsible for reorientation of the molecules.^{22–24}

2.6 Line Narrowing

All polyatomic gases possess more than one intramolecular relaxation mechanism. Even the molecule H_2 , for instance, has two competing mechanisms: the spin-rotation and the direct dipole-dipole interaction. In condensed phase molecular hydrogen the contribution of the dipole-dipole mechanism is comparable to that of spin rotation because the distance between the protons is short enough for the dipole-dipole relaxation to be appreciable. In a gaseous system, however, spin rotation is normally the dominant relaxation mechanism. In such experiments high density carbon dioxide can be added to hydrogen isotopomers such as hydrogen deuteride, as suggested by Johnson and Waugh,²³ to shorten the rotational correlation times and thereby lengthen the spin-rotation relaxation time and narrow the resonances in the high-resolution spectra. The H_2 system is difficult to study because of the indistinguishability of the two particles. Thus research on the lower HD symmetry^{18,19,21–23,25–28} provides more information from both the proton and deuteron resonances arising from indirect spin-spin couplings.

Supercritical fluids generally have viscosities 10–100 times lower than that of the normal liquid phase and self diffusion coefficients 10–100 times greater. To the NMR spectroscopist, these properties are of significant benefit in studying quadrupolar nuclei, since the quadrupolar linewidth is proportional to the rotational correlation time. The utility of NMR to study many quadrupolar nuclei has been somewhat limited. Quadrupolar relaxation can be very efficient, leading to broad lines and low sensitivities. In the extreme narrowing limit, the linewidth of these nuclei, $(1/\pi T_2)$ can be written as

$$\frac{1}{\pi T_2} = \frac{3}{8} \left(\frac{e^2 q Q}{h} \right)^2 \left(1 + \frac{\eta^2}{3} \right) \tau \quad (6)$$

where $e^2 q Q/h$ is the quadrupolar coupling constant, τ is the rotational correlation time for the molecular motion, and η is the asymmetry parameter of the electric field gradient

tensor. Various studies have demonstrated the validity of the Stokes–Einstein–Debye equation.²⁹

$$\tau = \frac{A\eta}{T + \tau_0} \quad (7)$$

in which τ is the rotational correlation time, η is the solvent viscosity, T is the temperature and τ_0 is the high temperature intercept. This equation predicts a linear relation between τ and η/T to a limiting value τ_0 attained in the limit as $\eta/T \rightarrow 0$. Comparisons with above equation show that NMR line widths should decrease with decreasing viscosity to a limiting value expected to be related to the free rotor correlation time given by

$$\tau_{\text{FR}} = \left(\frac{2\pi I}{9kT} \right)^{1/2} \quad (8)$$

where I is the moment of inertia about the rotational axis.

2.7 NMR Determination of Structural Dynamics in High-Pressure Fluids

There have been direct spectroscopic probes of the local solvent structure around solutes in supercritical fluids. These include using the solvatochromic scales as in the ultraviolet-visible (UV) absorption of phenol blue in ethylene³⁰ and the fluorescence spectroscopy of pyrene in carbon dioxide.³¹ The use of spectroscopic methods to study the local environment surrounding solute molecules in dilute supercritical fluid mixtures has been reviewed.³² However the use of NMR to determine the local structure within supercritical fluids has thus far been sparse in the literature.

2.7.1 High Pressure NMR Studies of Hydrogen Bonded Liquids

An understanding of molecular interactions between solute and solvent molecules in supercritical fluids (SCF) is essential to an explanation of clustering phenomena, considered responsible for the unique SCF solvating characteristics compared to gases.^{33–35} Although both theoretical^{36–38} and experimental efforts^{39–46} have been made to increase the understanding of these phenomena, a complete picture of clustering in SCFs is still evolving. The accumulation of experimental NMR relaxation data is expected to improve our physical picture of solvent clustering in SCF. Because the nuclear spin–lattice relaxation rates depend on the fluctuating molecular reorientation and molecular collision frequency, their measurement proves to be an effective method for studying such molecular interactions and dynamics in fluids.⁴⁷ One of the advantages of utilizing NMR relaxation data is that they provide not only information, similar to optical methods, on overall molecular motions but also site-specific information on intramolecular motions. The ^{13}C spin–lattice relaxation processes in CO_2 are dominated by spin–rotation interactions.^{48–50} Nuclear spin–lattice relaxation rates have been measured under SCF conditions by Lamb et al.⁵¹ and Etesse et al.^{52–54} for various SCF mixtures. NMR chemical shift measurements⁵⁵ were also used to relate ^{129}Xe chemical shift data to the local solvent structures of SCF Xe. SCF fluid structures in pure methanol,⁵⁶ CO_2 –methane,³⁹ CO_2 –methanol,⁴⁰ and CO_2 –decanol⁴⁰ mixtures have recently been made. The function of the hydroxyl

group in solute-induced solvent clustering in SCF CO_2 appears to be especially important. Earlier developments in high pressure NMR studies of hydrogen bonded liquids may be found in a review article by Lang and Ludemann.⁵⁷

Information on the nature and average rate of molecular motions may be obtained by determining the nuclear spin–lattice relaxation rates of nuclei in the molecules under investigation. The nuclear spin relaxation rate, $1/T_1$, depends on fluctuations in molecular reorientations as a consequence of molecular collisions, where T_1 is the time constant defining the exponential return of a perturbed nuclear spin to its equilibrium state. Many nuclear spin interaction mechanisms affect T_1 values. Among them, spin–rotation, quadrupolar and dipolar interactions are the most important ones at sub- and supercritical densities. Detailed descriptions of spin–rotation, quadrupolar and dipolar interactions may be found in the review articles by Grant et al.⁵⁸ and Jameson.⁵⁹ Briefly, determination of NMR nuclear relaxation rates provides the angular momentum⁵⁹ and rotational reorientation correlation times⁵⁸ from the spin–rotation and quadrupolar/dipolar interactions, respectively. Spin–rotation interactions are directly related to molecular collision frequencies and depend on macroscopic properties such as fluid density and temperature. Dipolar and quadrupolar interactions, however, are often related to fluid viscosity and temperature. Since the fluid viscosity may be treated as a function of local density in the compressible regions of CO_2 , both correlation times may be considered as functions of local densities. Therefore, clustering phenomena in SCF resulting in fluctuations of local density may in principle be observed by NMR relaxation measurements.

The magnitude of the NOE effect is given by⁶⁰

$$\text{NOE}(A\{X\}) = \frac{I_A^*}{I_A^0} \quad (9)$$

where I_A^* is the integrated intensity of a decoupled spectrum with saturation of the nucleus X , and I_A^0 is the equilibrium intensity of A in the coupled spectrum. The maximum possible NOE of $^{13}\text{C}\{^1\text{H}\}$ occurs when ^{13}C and ^1H relax only by the dipolar mechanism given by⁶⁰ and is given by

$$\text{NOE}(\text{max}) = 1 + \left(\frac{\gamma_{\text{H}}}{2\gamma_{\text{C}}} \right) = 2.988 \quad (10)$$

where γ_{H} and γ_{C} are the magnetogyric ratios for ^1H and ^{13}C , respectively. The NOE effect may be determined as a ratio of spectral intensities with proton decoupling to that of gated proton decoupling. Since the ^{13}C in CO_2 does not exhibit an NOE, its signal intensity may be used as a fiducial reference.

2.8 Significant Mechanism in Spin–Lattice Relaxation: Overall Rotational Motion

In general, the overall rotational motions of solute molecules depend on the intermolecular frictional forces between the solute and solvent molecules and, therefore, are dependent upon the solvent viscosity. The solvent viscoelastic response, in turn, is also dependent on various relaxation mechanisms of solvent molecules. Internal rotational motions including various local isomerization movements are driven by torsional forces.⁶¹

The rotational reorientation correlation time, τ_c , may be extracted from NMR spin–lattice relaxation time measurements, within the *extreme narrowing* limit, using the following expression⁶⁰

$$T_{1,DD}^{-1}({}^{13}\text{C}) = \frac{\nu\gamma_C^2\gamma_H^2\hbar^2\tau_c}{r^6} \quad (11)$$

where r is the bond distance between ${}^1\text{H}$ and ${}^{13}\text{C}$ (measured as 1.085 Å), and ν is the number of protons directly attached to the ${}^{13}\text{C}$ nucleus. The dipole–dipole relaxation rate, may be obtained from the standard relationship between the overall T_1 and NOE measurements:⁶⁰

$$\text{NOE} = 1 + \frac{\gamma_H}{2\gamma_C} \frac{T_{1,DD}^{-1}({}^{13}\text{C})}{T_{1,\text{Tot}}^{-1}({}^{13}\text{C})} \quad (12)$$

The reorientation correlation time obtained in this manner is an average assuming isotropic reorientation. This correlation time may be related to a rotational diffusion coefficient by assuming that each nuclear environment is roughly spherical and rotates randomly.⁶²

$$\tau_c = \frac{1}{6D} \quad (13)$$

From the temperature dependence of rotational diffusion coefficients at fixed viscosity, one can determine effective rotational activation energies.

2.9 CO₂ Clustering

The rotational reorientation correlation time, τ_c , can be expressed by a modified Stokes–Einstein–Debye (SED) equation⁶³

$$\tau_c = \frac{\eta V_p}{kT} f_{\text{stick}} C + \tau_0 \quad (14)$$

where η is the fluid viscosity, V_p is the volume of solute molecule, f_{stick} is a well-defined shape parameter dependent only on the structure of solute molecules,⁶⁴ C is a boundary parameter dependent on the nature of the solute and solvent and upon their concentration, and finally τ_0 is the free-rotor correlation time. The success of this model strongly depends on the selection of parameters C and f_{stick} . Recently, Roy et al.⁶⁴ noted that the Dote, Kivelson, and Schwartz (DKS) model⁶³ is the best model for predicting reorientational correlation times for solutes with radii up to about 4.5 Å. Anderson and Kauffman⁶⁵ further modified the calculation of the smallest volume of free space per solvent molecule, ΔV , in the DKS model, and more recently, these two workers⁶⁶ related fluid viscosity and the parameter C in the SED model to the local density by introducing a radial distribution function into the hydrodynamic model. These modifications^{65,66} by Anderson and Kauffman are referred to as the AK model.

In the AK model, the viscosity for a fluid is expressed as a function of local density ρ_{12}^1 by equation 4.7 described by Jossi et al.⁶⁷

$$[(\eta - \eta_0)\xi_T^y + 1]^{1/4} = 1.023 + 0.23364\rho_r + 0.58533\rho_r^2 - 0.40758\rho_r^3 + 0.09324\rho_r^4 \quad (15)$$

where $\rho_r = \rho_{12}^1/\rho_c$ and $\xi_T = (T_c/M^3 P_c^4)^{1/6}$. ρ_c , T_c , and P_c represent the critical density, temperature, and pressure, respectively. M is the molecular weight in the unit of g mol⁻¹. The local density of is related to the bulk density ρ by a radial distribution formalism

$$\rho_{12}^1 = \rho\{1 + F[g_{12}(r)]\} \quad (16)$$

where $F[g_{12}(r)]$ is an integral equation in the pair distribution function, $g_{12}(r)$, over the spatial coordinates and r is the distance between solvent and solute molecules. $F[g_{12}(r)]$ is a measure of the excess solvent density near the solute molecule and is treated as an adjustable parameter in the AK model. When $F[g_{12}(r)] = 0$, the local density equals the bulk density, and when $F[g_{12}(r)] = 1.0$, the local density is twice the bulk density.

In the AK model, the parameter $C(\rho_{12}^1)$ equivalent to C in the SED model, is also treated as a function of local density. According to the DKS model

$$C(\rho_{12}^1) = \frac{f_{\text{slip}} V_p}{f_{\text{slip}} V_p + \gamma V_p} \quad (17)$$

where f_{slip} is a factor for the slip boundary condition whose value estimated from f_{stick} by the method reported by Hu and Zwanzig⁶⁸ and γ is defined as

$$\gamma = \left(\frac{\Delta V}{V_p}\right) \left[4 \left(\frac{V_p}{V_s}\right)^{\frac{2}{3}} + 1\right] \quad (18)$$

In equation (18), V_s is the solute molecular volume and ΔV is the free space volume for a solvent molecule. For supercritical fluids in their compressible regions, a large variation in the free space is expected, and ΔV is given by equation (19) relating molecular weight (MW) and local density:

$$\Delta V = \frac{\text{MW}}{\rho_{12}^1} - V_s \quad (19)$$

Therefore, the parameter $C(\rho_{12}^1)$ is expressed as a function of local density ρ_{12}^1 though the free space volume ΔV .

Combining equations (18) and (19), the AK version of the SED equation may be expressed as⁶⁶

$$\tau_c \equiv \frac{\eta(\rho_{12}^1) V_p}{kT} f_{\text{stick}} C(\rho_{12}^1) + \tau_0 \quad (20)$$

Equation (20) relates the reorientation correlation time, τ_c , to the solvent local density at a given temperature. By performing a comparison experiment on *trans,trans*-1,4-diphenylbutadiene (DPB) solute in CO₂, Anderson and Kauffman⁶⁶ also observed that CO₂ solvent clustering only occurs in the vicinity of *trans*-4-(hydroxymethyl)stilbene (HMS) molecules. Because the extended π -electron systems existing in DPB and HMS are similar, Anderson and Kauffman concluded that the OH group in HMS is responsible for the association between the solute and solvent molecules. The one-to-one association between solute and solvent molecules may initiate further CO₂ clustering whenever strong many-body interactions affect the solvent structure in supercritical

fluids in the compressible density region. The CO₂ clustering gradients observed along the aliphatic chain of 1-decanol molecules in the Bai et al.³⁹ study appear to support the observations by Anderson and Kauffman.

To verify further the importance of alcohol enhanced clustering, the same procedure was applied to a CO₂–methanol mixture,⁶⁹ where a specific association between CO₂ and CH₃OH has been observed also by the IR studies.⁴² Such solvent-solute interactions may initiate CO₂ solvent clustering.⁶⁶ The low-pressure limit free-rotor correlation time can be calculated using the following expression⁷⁰

$$\tau_0 = \frac{2\pi}{9} \left(\frac{I_{\perp}}{kT} \right)^{1/2} \quad (21)$$

where $I_{\perp}$ is the perpendicular component of the moment of inertia for methanol molecules. The calculated τ_0 from equation (21) is 0.20 ps, which agrees well with the 0.17 ps from fitting the low-density data.

2.10 More Evidence for the Formation of CO₂ Clusters in the Vicinity of Methanol

As stated above, NOE measurements allow the separation of the dipole–dipole contributions to spin–lattice relaxation rates from other mechanistic contributions. For methanol, the remaining relaxation contributions result essentially from the spin–rotation mechanisms described previously.⁶⁹ These spin–rotation relaxation rates allow one to calculate an angular momentum exchange correlation time, τ_J , which is strongly dependent on the fluid density. Methanol is a quasi-symmetric top molecule, but the relation between ρ , and spin–rotation relaxation rates for symmetric top molecules may be used as a good approximation for T_1^{SR} . The expression⁷¹ is

$$\frac{1}{T_1^{\text{SR}}} = \frac{2\pi^2}{\alpha} C_{\text{eff}}^2 \tau_J \quad (22)$$

where pull down $\alpha = \hbar^2/(2kT I_{\perp})$ and $I_{\perp}$ is the perpendicular part of the moment of inertia for methanol. The effective spin–rotation, C_{eff} , may be expressed as

$$C_{\text{eff}}^2 = k_1 C_a^2 + k_2 C_a C_d + k_3 C_d^2 \quad (23)$$

In equation (23), the structure parameters, k_i , only depend on molecular structure. C_a and C_d are the isotropic and anisotropic components of the spin–rotation tensor. Therefore, in principle, an experimental angular momentum correlation time, τ_J , may be estimated using equation (22). Since τ_J is linearly related to the time between molecular collisions, τ_{BC} , one may calculate τ_J using a gas kinetic theory. The slope of this linear relationship, called an effective collision number and referred to as Z ,⁷² provides the average number of collisions needed for an effective molecular angular momentum exchange. This number is found to be between 1.4 and 3.4 for many collision pairs (cf. Table 3 in Ref.⁷²). In the use of a hard-sphere model (HSM) for calculating cross sections, choosing the effective collision number of two appeared to be a good approximation in the work of Maryott, Malmberg,

and Gillen,⁷² and therefore, this value is used in the following discussion. The expression for computing τ_J is given by⁷³

$$\tau_J = \frac{Z}{\rho \bar{v} \sigma_K} \quad (24)$$

where ρ is fluid density, $\bar{v}$ is the average velocity of molecules, and σ_K is the kinetic collisional cross section between solute and solvent molecules. Both $\bar{v}$ and σ_K may be estimated from molecular properties of the solute and solvent. If the density term, ρ , in equation (24) is replaced by a local density [cf. equation (16)], the estimated τ_J becomes a function of the excess solvent density parameter, $F[g_{12}(r)]$. In this case, equation (24) becomes

$$\tau_J = \frac{Z}{\rho \{1 + F[g_{12}(r)]\} \bar{v} \sigma_K} \quad (25)$$

There is good agreement between theoretical and experimental data when an increase in local density is employed in the predictions of τ_J . This provides additional evidence for the formation of SCF solvent clustering in the vicinity of hydrogen bonding solute molecules. Supposedly, these interactions are induced by the hydroxyl functional group present in alcohol molecules.

2.11 NMR Determination of Self-diffusion Coefficients in High-pressure Fluids

Many methods exist for measuring the diffusion coefficients of fluids. However, the experimental accuracy of many of these is quite limited.^{74,75} Furthermore, methods that give reliable results in the low pressure regime are not always suitable at high pressures because the inverse dependence of the diffusion coefficient on pressure makes for experiments that take an inordinately long time. The most widely reported method for the measurement of diffusion coefficients in the SCF state is a gas chromatographic method based on Taylor dispersion, which has proven unreliable at lower pressures.^{76–78}

The only other methods that can be utilized for this measurement in SCFs are photon correlation spectroscopy^{79,80} and NMR.^{81,82} They are not widely used at this time because the equipment is very expensive and their application to industrially important SCF's is still in its infancy. The use of the NMR technique has been confined to the measurement of self diffusion coefficients.^{81,82}

3 INSTRUMENT REQUIREMENTS FOR HIGH-PRESSURE NMR

In order to perform NMR experiments under high pressure, it is necessary to devise a convenient means to control the pressure, temperature and sample concentration while it is inside the magnet. Two basic approaches to the design of high pressure NMR experiments have been reported: (1) construction of a probe which is capable of achieving the necessary pressures, referred to as the *high pressure probe technique*,⁸³ or (2) fabrication of a high pressure cell which can be used in a standard commercial NMR probe, referred to as the *high pressure cell technique*.

The very first high pressure NMR experiment was performed in 1954 by Benedek and Purcell.⁸⁴ They used a

hydrostatic high pressure probe capable of holding pressures up to 10 000 atm. For deformable samples the high pressure probe technique requires a sealed sample cell which incorporates a volume change mechanism such as bellows or a mercury column.⁸⁵ The cell is surrounded by a RF coil and is located inside a pressure vessel small enough to fit inside the NMR magnet. The high pressure probe technique usually offers higher sensitivity because of a better filling factor for the receiver coil. It also allows for higher pressures and is usually safer to work with. The disadvantages are that they require a more elaborate and expensive design and are therefore not suitable for a routine NMR laboratory. The approach to a high pressure probe has continually been developed by Jonas et al.⁸⁶ with improvements to pressure vessel design and electrical feed-throughs. The most recent advances to the probe design for studying supercritical fluids include the toroidal coil⁸⁷ and cavity⁸⁸ design by Rathke et al.

The high pressure cell technique allows the experiments to be performed in a commercial NMR probehead, thereby eliminating the need to alter the basic probe design. The earlier versions of high pressure cells experienced lower sensitivity and reduced working pressures. Yonker et al. designed a simple and safe method by coiling a fused silica capillary tube inside a commercial 5-mm NMR tube.⁸⁹ Newer cell designs have improved these limitations providing a more convenient and cost-effective means of carrying out high pressure NMR experiments. Roe et al.⁹⁰ designed the first cell made of single crystal sapphire and Horvath et al. later improved this design.^{91,92} Pressure control while the cell is in the magnet is a major issue in the cell design. The previously reported designs of the sapphire NMR cells were unable to independently control both the sample temperature and pressure. In the Bai et al. design⁹³ a movable piston is used to control the sample pressure (see Figure 2). With this design it is possible to control temperature and pressure independently over a wide range of conditions while keeping the relative molar concentration ratios of the sample mixture intact. The sample volume must be restricted to the active coil in order to eliminate errors introduced through molecular diffusion between polarized and nonpolarized volume elements within the cell. Recently a high pressure cell constructed of high-performance polymers, such as poly(etherether ketone) (PEEK), was developed by Wallen et al.⁹⁴ with the purpose of simplifying the cell design to allow for more routine experiments on supercritical fluids.

The very first high pressure probe was made of a beryllium copper alloy (Berylco 25). This alloy was used due its strength and nonmagnetic properties, but does require special heat treatment and can have significant variations in the level of paramagnetic impurities. Berylco 25 is stable up to 10 000 atm and permits a temperature range of -10°C – 80°C . Titanium alloys (IMI-680) are now more commonly used as they require no special heat treatment during machining and retain their strength up to 400°C and 5000 atm. For even higher pressures, up to 100 kbar, the diamond anvil method can be used.⁹⁵ This method can only be used with very small samples so most studies concern sensitive nuclei, although a study on ^{13}C has been reported.

4 SUPERCRITICAL FLUID APPLICATIONS

Most of the high pressure NMR studies of supercritical fluids have involved measuring chemical shifts, such as ^1H ,⁹⁶

Figure 2 Schematic diagram of the high pressure piston NMR cell capable of independently controlling temperature, pressure and sample concentration

of both polar and nonpolar solute molecules in the dense phase fluid. Increased reaction rates of certain reactions in supercritical fluids has been attributed to specific solvent-solute and solute-solute interactions. By studying these specific interactions by NMR further insight into the variation of the surroundings of the solute molecules with the density of the supercritical fluid is obtained and can be compared to other experimental techniques, such as UV and vibrational spectroscopy.

Using a fused silica capillary cell an in situ photolysis study of organometallics in supercritical fluids was performed where the ligand exchange with the metal center was directly observed.⁹⁷ High pressure NMR was also used to determine the fundamental dynamic and electronic properties of the organometallic complexes in the SCF through the investigation of the spin-lattice relaxation times, T_1 , and NMR magnetic shielding constants, σ .

Another interesting application of supercritical fluids is to use them as solvents for comprehensive NMR studies of large proteins. In conventional solvents large proteins (over 30 kDa) tumble too slowly and correspondingly the spin-spin relaxation times (T_2) become shorter, making some standard experiments unreliable. By encapsulating the protein in a reverse micelle dispersed in a low viscosity fluid, such as a supercritical fluid, the tumbling correlation time (τ_m) of the protein is reduced thereby increasing T_2 .⁹⁸ This results in narrower lines in the spectrum.

High pressure NMR has also been used to investigate phase behavior of binary solvent systems in order to obtain vapor-liquid equilibrium (VLE) values. Usually VLE values of supercritical fluid solutions are obtained using variable volume view cells and off-line analysis techniques. By using NMR, this process can be simplified and made more efficient for numerous solvent systems. This technique is especially suitable for hydrocarbon containing solvent molecules as detection of solvent protons in both the liquid and vapor phase can be detected simultaneously.⁹⁹

An advantage of using supercritical fluids as reaction media for chemical reactions is that gaseous reagents are completely miscible with the solvent. In catalytic reactions such as hydrogenations and hydroformylations where H_2 and CO are reactants this can have a significant impact on both the yield and selectivity of the desired products. Since only one phase is present in the supercritical system, stirring to achieve gas-liquid mixing is unnecessary. By studying these reactions in situ by NMR valuable information regarding the mechanism can be obtained.¹⁰⁰ In situ NMR was used to optimize the iridium catalyzed enantioselective hydrogenation of imines in supercritical CO_2 . By studying the specific interactions between substrates and products with CO_2 conclusions about the different reactivities of structurally similar substrates were obtained.¹⁰¹

1 INTRODUCTION

Transferrins are a family of metal binding glycoproteins which play a fundamental role in iron metabolism in vertebrates and invertebrates.¹ Transferrin from serum (Tf hereafter) acts as the principal iron carrier in plasma, binding the Fe^{3+} ion strongly and reversibly and shuttling it from the sites of metal uptake to those of iron-proteins biosynthesis and iron storage. Ovotransferrin from avian egg white (Otf), and lactoferrin (Ltf) found in many secretory fluids and in leukocytes, are mainly iron-sequestering proteins which exert a bacteriostatic and detoxifying function. Transferrins are monomeric proteins of about 700 residues with molecular weight close to 80 kDa. They are related by a sequence homology of about 50%. The X-ray structural information^{2,3} indicates that the polypeptide chain is organized into two nearly equal-sized and about 40% homologous globular lobes connected by a short peptide segment, each containing one chain terminus (hence termed N-lobe and C-lobe), and one metal site (Figure 1). Each lobe is in turn structured into two domains. The metal lies at the bottom of the cleft between the two domains, about 10 Å from the protein surface. Both metals are bound by two tyrosines, one histidine, and one aspartate in a pseudooctahedral coordination which is completed by a bidentate carbonate ion hydrogen bonded to some protein groups (Figure 1).^{2,3} X-ray data also indicate the absence of metal-coordinated water in the crystal.

The requirement of a concomitant (synergistic) binding of an anion (besides carbonate, carboxylate anions with a second donor group are also active) for specifically loading the metal in the two sites is a unique feature of the biochemistry of transferrins. In recent years X-ray crystallography and NMR have allowed the elucidation of several molecular details of the metal sites. It is apparent that the formation of the ternary complex at both sites proceeds through initial anion binding to the protein: the anion is most probably required to reduce the net positive charge in the binding cavity, due to the presence of a number of cationic residues, and for increasing the overall stability of the adduct by further anchoring the metal to the protein. Overall, it functions as a bridge between the metal and the protein. The synergistic anion appears to play a central role in the reactivity of the metal centers, acting as the key for the processes of metal uptake and release. The associated protein conformational changes are also being extensively studied, in

Figure 1 (a) $\text{C}\alpha$ plot of the lactoferrin molecule showing its subdivision into two lobes, the N-lobe (top) and C-lobe (bottom). The iron atoms are shown as filled circles bound in the cleft between the two domains in each lobe. (b) The metal- and anion-binding site in lactoferrin (N-lobe). The carbonate anion is shown by hatched circles. Hydrogen bonds are indicated by dotted lines. (Reproduced by permission of Academic Press from B. F. Anderson, H. M. Baker, G. E. Norris, D. W. Rice, and E. N. Baker, *J. Mol. Biol.*, 1989, **209**, 711)

particular the open–close equilibrium of the interdomain cleft at each lobe, with metal binding and removal occurring only in the open form.

The two metal sites of transferrins are, in general, spectroscopically slightly inequivalent and differ, although most often not dramatically, in metal binding affinity. The relative binding strength of the two sites is sensitive to pH, synergistic anion, and ionic composition of the medium, and may vary toward different metals. However, the C-site almost invariably shows a greater metal affinity than the N-site at acidic pH. The structural bases of these differences are still not unequivocally

established (although the disulfide bridge content of the two lobes appears to be relevant in this respect). Their physiological relevance is also under investigation. The biological requirement for the structural 'doubleness' of transferrins is nowadays a central issue.

Transferrins can firmly bind a large number of transition, nontransition, and lanthanide ions. Several metals have served as spectroscopic probes for investigating the structural features of the metal sites, but some of the adducts also have a biological relevance since serum transferrin, being only about 30% saturated with iron in vivo, may function as an efficient carrier for metals other than iron.

2 THE ROLE OF NMR IN THE CHEMISTRY OF TRANSFERRINS: ACHIEVEMENTS

It should be recalled that for a protein of the size of transferrin full structural studies in solution (see *Biological Macromolecules: Structure Determination in Solution; Biological Macromolecules; Biological Macromolecules: NMR Parameters; Multidimensional Spectroscopy: Concepts; Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*) are not yet feasible. The NMR of transferrins was until recently mainly devoted to the elucidation of the molecular details of the ternary adducts at the metal sites with the following methodological approaches: (a) ^{13}C NMR of protein derivatives of diamagnetic metals with ^{13}C -enriched anions; (b) observation of protein-bound NMR active metal nuclei; (c) observation of ^1H NMR hyperfine-shifted resonances arising from the protons surrounding a bound paramagnetic metal (see *Electron-Nuclear Hyperfine Interactions; Cobalt(II)- and Nickel(II)-Substituted Proteins; Electron-Nuclear Multiple Resonance Spectroscopy*); (d) NMRD profiles. Only in recent years, has one- and two-dimensional ^1H NMR at high field (see *Multidimensional Spectroscopy: Concepts*) succeeded in handling, at least partially, the largely unresolved proton spectrum and proved to be of use in monitoring metal binding to the protein and the related conformational changes. In what follows we have outlined the contribution of NMR to the understanding of the main issues of the metallobiochemistry of transferrins.

2.1 Identification of the Metal-Binding Residues

The involvement of tyrosine residues in metal binding at both sites of transferrins, indicated by a number of spectroscopic and chemical modification studies, has been conclusively supported by ^1H NMR since the early 1970s from the shift induced in the corresponding resonances by Ga^{3+} binding, and their paramagnetic broadening upon Fe^{3+} binding (see *Paramagnetic Relaxation in Solution*).⁴ In addition, two histidines were also proposed as metal ligands from the detection of the C(2)H resonances which did not titrate with pH in the Ga^{3+} ternary complexes⁵ of either intact or half molecules of Otf and human Tf.^{6,7} (Ga^{3+} has proved to be a good diamagnetic substitute for the Fe^{3+} ion, owing to the similarity of the ionic radius and to a similar binding affinity for transferrins). Metal binding of two histidines and two tyrosines was also consistent with the hyperfine shifted ^1H

resonances in the mono- and bis- Co^{2+} derivatives of Otf.^{8,9} The spread of the hyperfine shifted signals and their relatively long relaxation times¹⁰ (see *Paramagnetic Relaxation in Solution and Cobalt(II)- and Nickel(II)-Substituted Proteins*) suggested octahedral coordination around the metal ions.^{8,9}

The X-ray structure later confirmed octahedral coordination and the presence of two tyrosine ligands, but showed that only one of histidine is involved in the metal binding site.^{2,3} The identity of the additional nontitrating histidine in the Ga^{3+} derivative remains unknown, while the additional hyperfine shifted exchangeable proton in the spectrum of the Co^{2+} derivative could well arise, in retrospect, from one of the NH protons H bonded to the metal-coordinated carbonate ion.

Cadmium-113 NMR¹¹ (see *Cadmium-113 NMR: A Surrogate Probe for Zinc and Calcium in Proteins*) and ^{205}Tl NMR data¹² (see *Thallium NMR*) are in full agreement with the presence of only one histidine in the binding set. Aspartate coordination invariably went undetected, most probably due to the rather elusive ^1H NMR spectral changes in the crowded aliphatic region upon metal binding and the impossibility of metal NMR to discriminate it from other potential oxygen donors.

2.2 Exchangeable Protons in the Metal Sites

The issue of possible water coordination was tackled through water proton relaxation measurements. Early studies of water T_1 measurements in solutions of the Fe^{3+} adducts of Htf and Otf simply showed the accessibility of both sites to water molecules.^{13,14} This was substantiated later by measurements of the field dependence of the longitudinal nuclear magnetic relaxation rates of water protons (NMRD profiles) on the iron adduct of Htf, also carried out for comparative purposes on the apoprotein and the diamagnetic analog containing Co^{3+} , which were interpreted as indicative of a water molecule only loosely bound to the metal in each site.^{15,16} Analogously, one water molecule axially bound to the metal was also proposed for the Cu^{2+} derivative of Htf.¹⁷ It was later shown that for slowly rotating protein complexes the anisotropic structure of the ligand fields of the complexed metals is not averaged out as it is for fast rotating aqua ions or small complexes.^{18,19} The NMRD profiles for Cu^{2+} and VO^{2+} complexes of Htf were then evaluated with computations that included the anisotropic hyperfine interaction of metal ions with their own nuclei (see *Electron-Nuclear Hyperfine Interactions*).²⁰ It was found that relaxation occurs through exchange of bulk water with a second coordination sphere water molecule. This was also confirmed for the Gd^{3+} -Htf complex²¹ (see *Gadolinium Chelates: Chemistry, Safety and Behavior*) and demonstrated later by the X-ray structure of human Ltf.³ Recent²² more quantitative interpretation of the NMRD data for Fe^{3+} -Htf,²³ taking into account zero field splitting of the iron ion,^{18,19,24} suggests the presence of slowly exchanging protons (possibly from the protein) and of fast exchanging water at about 4–5 Å from the metal ion. NMRD data on Cu^{2+} -transferrin were also instrumental in demonstrating rotation-independent electronic relaxation mechanisms for Cu^{2+} in solution.²⁵

2.3 Synergistic Anions in the Metal Sites

Elucidation of the anion binding arrangement in the metal sites was obtained from a number of ^{13}C NMR data using

Table 1 ^{13}C NMR Chemical Shifts for ^{13}C -Enriched Synergistic Anions in Various Metal–Transferrin Derivatives^a

Derivative	Chemical shift ^b	
Carbonate derivatives		
Co ³⁺ – Htf ²⁷	169.5	169.3
Al ³⁺ – Otf ³⁰	165.7 (N)	165.5(C)
Al ³⁺ – Htf ²⁹	165.4

Cd ²⁺ – Htf ³²	168.5 (C)	169.9 (N)

^aHtf: human serum transferrin; Otf: ovotransferrin; Ltf: human lactoferrin. Assignments to the N- and C-site are reported in parentheses, when available.

^bIn ppm from Me_4Si .

^{13}C -enriched anions (mainly carbonate and oxalate) and/or NMR-active nuclei loaded in the protein sites. The spectral parameters and resonance assignments to individual sites, where available, have been collected in Table 1 and 2. The broadening beyond detection of the ^{13}C NMR resonance of isotopically-enriched bicarbonate bound to Fe^{3+} –Tf²⁶ allowed an estimate to be made of an upper limit of 9 Å for the Fe – ^{13}C distance, which was later reduced to 4.5 Å²⁷ thanks to instrumental developments, consistent with the presence of the anion in the first coordination sphere of the metal. The latter study also indicated that the anion, most probably carbonate rather than bicarbonate as judged by the ^{13}C chemical shift value, was specifically bound in both metal binding sites of the diamagnetic Co^{3+} derivative and of the apoenzyme, giving rise in both cases to resonances in slow exchange with that of free bicarbonate (see *Chemical Exchange Effects on Spectra*).²⁷ Specific anion binding to the apoprotein was taken as indicative that anion binding to the sites may precede metal binding, which is now indeed a widely accepted step in the mechanism of metal uptake of transferrins. A positively charged arginine residue was suggested as one of the anion

binding groups for carbonate,²⁷ as later confirmed by X-ray data. The pH dependence of the ^1H NMR resonances of the histidine C(2)H protons in diamagnetic $\text{Ga}(\text{III})$ derivatives of Otf, Htf, and their half-molecules in the presence of dicarboxylic acids as synergistic anions indicated a histidine as the likely anion binding group in each site.^{5–7,28} Interestingly, the X-ray structure of human Ltf allows for binding of anions larger than carbonate not to the arginine involved in the carbonate derivative, but to polar residues of a cavity beyond such a residue, which actually also includes a histidine residue.³

Further ^{13}C NMR studies of diamagnetic Al^{3+} –, Ga^{3+} – and Zn^{2+} –transferrin derivatives with carbonate and oxalate as the synergistic anion^{29,30} were interpreted in terms of the anion bridging the metal and a positively charged group of the protein, in line with the ‘interlocking-sites’ model (Figure 2).³¹ Oxalate bound in the Ga^{3+} – and Al^{3+} –Otf derivatives gave rise to two partially overlapped AB signal patterns.²⁹ The inequivalence of the two carbon atoms was assumed to arise from oxalate binding to the metal via only one carboxylate group, the other interacting with a positive residue of the site. Reference to ^{13}C chemical shift data of simple inorganic oxalate complexes allowed the assignment of the resonances of the protein-bound and metal-bound carbons of each oxalate molecule.^{29,30} In the case of Zn^{2+} –²⁹ and Cd^{2+} –Otf–oxalate derivatives,³² the effect of the metal on the shielding of the carbon atom is more similar to that of the protein residue, leading to the equivalence of the two carbon atoms (see *Magnetic Equivalence*), hence to the observation of a single signal for each protein-bound anion.

Overall, although subject to a successive reevaluation (see below), these ^{13}C NMR data strongly supported the bridging arrangement of the synergistic anion prior to publication of the X-ray data.^{2,3} Moreover, more recent ^{113}Cd NMR spectra of the ^{113}Cd –Otf derivative with glycine as the synergistic anion unequivocally indicated the binding of the amino group of the amino acid to the metal, fully in line with the interlocking sites model.³³

Observation of the magnetic coupling between an $I = \frac{1}{2}$ metal and the carbon atom of the anion in both metal sites yielded conclusive spectroscopic evidence of a direct metal–ion linkage. In particular, this was achieved by using ^{205}Tl and ^{113}Cd ions loaded in one or both metal sites (Figure 3).^{11,12,34} The 2J coupling constants are collected in Table 2.

Thallium–transferrin derivatives allowed a reevaluation of the binding mode of oxalate, and led to further insight into the chemistry of the ternary adduct in the protein sites. The ^{13}C NMR signals of bound oxalate in each site of the $^{205}\text{Tl}^{3+}$ derivatives of human Tf and Otf are split into a doublet of doublets due to carbon–carbon and thallium–carbon coupling.¹² The comparable values of the ^{13}C –metal coupling constants for the two oxalate carbons (Table 2) indicate that the anion binds to the metal in a 1,2-bidentate mode at both sites. This is likely to be the case for all the oxalate adducts of transferrins with tripositive metals, as recently suggested from the similarity of the ^{13}C NMR spectral patterns for these adducts.¹² This view receives conclusive support from the X-ray structure of the Cu^{2+} –oxalate ternary adduct with the C-terminal half-molecule of Ltf,³⁵ which confirms the 1,2-bidentate bridging arrangement of the oxalate anion and indicates that the spectral inequivalence of the two carbon

Table 2 Spectral Parameters for Metal NMR Resonances and M–¹³C Coupling Constants for Various Metal–Transferrin Derivatives^a

atoms in the ternary adducts with tripositive metals arises from differences in the protein residues H bonded to the two carboxylate groups. In the light of these results, the ¹³C spectra of the ¹¹³Cd²⁺–oxalate adduct of Otf, for which, unlike the carbonate derivative,¹¹ no ¹¹³Cd–¹³C coupling could be detected,³² consistent with a longer metal–carbon distance, can also be interpreted in terms of the above anion arrangement.

Recent work on NMR of quadrupolar metal nuclei (⁵¹V, ²⁷Al, and ⁴⁵Sc) (see *Aluminum-27 NMR of Solutions; Quadrupolar Transition Metal and Lanthanide Nuclei*) loaded in the sites of transferrins deserve a special mention.^{12,30,36–40} For an $I = \frac{n}{2}$ nucleus ($n = 3, 5, 7$) firmly bound to a slowly rotating macromolecule, far from the extreme narrowing limit, it is shown that only the central $\frac{1}{2} \rightarrow -\frac{1}{2}$ nuclear spin transition can be observed (see *Quadrupolar Interactions*) (Figure 4). Under these conditions the field dependence of the linewidth and chemical shift (see *Dynamic Frequency Shift*) provides the values of the quadrupole coupling constant, χ , and of the rotational correlation time, τ_c , for the protein-bound metals, and hence yields information

on the symmetry of the metal coordination environment. For example, independent of the synergistic anion, the Al³⁺ ion appears to be octahedrally coordinated in both sites, with a higher degree of symmetry in the N-site as compared to the C-site.³⁰ Moreover, the metal sites of the Sc³⁺–Otf derivative show a higher symmetry than those in the homologous Al³⁺ derivative.³⁸

Since detection of the resonances of these quadrupolar nuclei is facilitated by increasing the magnetic field and the molecular size of the protein, the technique is of general interest for probing the properties of the metal binding sites of large metalloproteins.

2.4 The (In)Equivalence of the Two Binding Sites

Early water proton relaxation measurements of Fe³⁺ binding to Otf, coupled with electrophoretic profiles, failed to detect the difference in iron binding ability of the two sites,⁴¹ indicating a random distribution of iron in the two lobes.¹⁴ Inequivalences can be detected with the aid of paramagnetic

Figure 2 75.4 MHz ^{13}C NMR spectra of the carbonyl region of (A) Otf-carbonate-metal complexes and (B) Otf-oxalate-metal complexes in the presence of excess anion, pH 8 (protein concentration 1.5 mM): (a) apoprotein; (b) Al^{3+} derivatives; (c) Ga^{3+} derivatives; and (d) Zn^{2+} derivatives. (Reproduced by permission of the American Chemical Society from I. Bertini, C. Luchinat, L. Messori, A. Scozzafava, G. C. Pellacani, and M. Sola, *Inorg. Chem.*, 1986, **25**, 1782)

metals like Co^{2+} ^{8,9} and lanthanides,⁴² taking advantage of the sensitivity of hyperfine shifts to even slight changes in the coordination sphere.¹⁰ The advent of high-field Fourier transform spectrometers allowed the safe determination of site (in)equivalence simply from the presence of either one or two NMR signals (or signal patterns) due to the ^{13}C -labeled synergistic anion and/or NMR-active diamagnetic metals bound to the protein. A metal titration then generally indicated if sequential metal binding had occurred, and in some instances assignment of the NMR resonances to the individual sites allowed the site with higher metal affinity to be determined. This approach has been followed for the derivatives of Otf and Htf with Co^{3+} , Ga^{3+} , Al^{3+} , Tl^{3+} , Sc^{3+} , V^{5+} , Cd^{2+} , Zn^{2+} in combination with different synergistic anions, most often carbonate and oxalate. The NMR-active metals and the ^{13}C -labeled synergistic anion loaded in the two sites led to either overlapping peaks or distinct, but invariably closely spaced, resonances indicative of equivalent (within the resolution available) or slightly different chemical environments, respectively (Table 1 and 2). The higher metal affinity of the C-site over the N-site at acidic pH was, in general, exploited to obtain resonance assignment to individual sites, although recently the use of proteolytically-obtained half-molecules has proved to be a safer means for such an assignment. This was evidenced for the derivatives of human Tf and Otf with Al^{3+} , Tl^{3+} , and Sc^{3+} , for which the metal resonances and the ^{13}C signals of the synergistic anion in the bimetallic derivative were invariably found to exactly superimpose the signals of the two one-sided half-molecules.^{12,30,36–38}

These extensive NMR data concurred to indicate that the relative properties of the two sites for a given transferrin vary with the nature of the metal, the synergistic anion, pH, and medium composition, and may differ from those of other transferrins. The following selected examples are worth mentioning. Aluminum-27 and ^{13}C NMR showed that in the presence of carbonate the two aluminum metal sites of Otf are slightly inequivalent and that Al^{3+} binds preferentially to the N-site at pH 8, while the site preference is reversed with oxalate.³⁰ In contrast, spectroscopically equivalent sites are detected in the homologous derivatives of human Tf and Ltf.³⁶ At pH values slightly above neutrality in the presence of carbonate, the Tl^{3+} ion was shown at an early stage,⁴³ unlike Al^{3+} , to bind more strongly to the C-site of human Tf, and more recently to bind with the same affinity to both sites of Otf.¹² Moreover, Sc^{3+} showed no site preference toward Otf with either carbonate or oxalate as synergistic anions,³⁸ and site inequivalence in the Cd^{2+} derivative of Tf with oxalate appeared more pronounced than in the homologous Zn^{2+} derivative.^{11,32}

Although this overview demonstrates NMR to be a powerful tool for probing the differences in structural properties and binding affinity of the two metal sites, at present, as noted elsewhere,⁴⁴ it does not address unequivocally the question of the presence of a functional association between the lobes. The above-mentioned near-identity of the spectral properties of a given site in the half and intact transferrin molecules does not necessarily imply that the metal affinity of the sites remains unchanged upon proteolytic cleavage.

The application of resolution enhancement techniques, although allowing resolution of only a small fraction of the total proton resonances, particularly those belonging

to relatively mobile portions of the protein, has recently enabled one- and two-dimensional ^1H NMR (see *COSY Two-Dimensional Experiments; Multidimensional Spectroscopy: Concepts; NOESY*) to monitor the binding of diamagnetic metals to whole and half-transferrin molecules.^{45–47} Low-frequency methyl peaks probably experiencing aromatic ring

current shifts, glycan *N*-acetyl and sugar ring protons, Lys/Arg $\epsilon/\delta\text{-CH}_2$ protons, and His C-2,H resonances could be resolved in the apo form of human Tf.⁴⁷ The disappearance of some of these peaks and the rise of new resonances in a slow exchange regime upon metal titration of the apo form of whole human Tf and its N-lobe (HTf/2N hereafter) allowed the detection of the sequential binding of Al^{3+} and Ga^{3+} to Tf, with preferential binding of the former metal to the N-site (in the presence of carbonate, pH 8.8),⁴⁶ and of the latter to the C-site (with oxalate as a synergistic anion, pH 7.2).⁴⁵ Examples of one- and two-dimensional proton spectra are illustrated in Figure 5.⁴⁵

Since X-ray data indicate that the structural features of the N-lobe are likely to be closely similar in the intact protein and in the isolated lobe,² the lack of a perfect match between the spectral features of the apo form and the Al^{3+} adducts of Tf and Tf/2N was interpreted as indicative of an interaction between the lobes in the intact protein.⁴⁶ This approach also allowed a determination of the apparent binding constant of oxalate to apo-HTf/2N ($\log K = 4.04 \pm 0.09$) from the shift of some resonances induced by the weak binding of the anion, as a consequence of the fast exchange between the free and anion bound species on the NMR timescale.⁴⁵ Moreover, the time course of the paramagnetic broadening of the proton resonances in the Ga^{3+} -oxalate-HTf/2N adduct upon Fe^{3+} addition allowed the kinetics of Ga^{3+} displacement ($k_{\text{obs}} = 0.162 \text{ h}^{-1}$ at 310 K) to be determined.⁴⁵

2.5 Other Structural Features in Solution

Tentative assignments of the low-frequency methyl proton resonances to individual Leu, Val, and Ile residues were proposed for human Tf and its N-lobe through 2D COSY techniques (see *COSY Two-Dimensional Experiments*) and calculation of the shifts induced by the ring currents of nearby aromatic groups (see *Shielding: Overview of Theoretical Methods*).^{45,46} The shifts of these resonances upon metal binding appear to be related to changes in their orientation toward the aromatic groups which reside in relatively mobile, yet structured hydrophobic domains possibly involved in conformational changes related to the closure of the interdomain cleft.⁴⁵ Unambiguous signal assignments and determinations of the precise movements of single residues are still unavailable, but much effort is being devoted toward this end.

Nonsynergistic anions like chloride, perchlorate, thiocyanate, and pyrophosphate are known to decrease the stability of various metal-transferrin derivatives, and, the chloride ion in particular, to affect the relative metal binding affinity of the sites.⁴⁸ They most probably bind to positively charged residues in the proximity of the metal site, altering the network of salt bridges and hydrogen bonds that stabilize the complex. The effect of perchlorate in decreasing the stability of the metal complexes was clearly monitored by the decrease of the ^{13}C and ^{113}Cd NMR resonances of the $^{113}\text{Cd}_2\text{-Otf-CO}_3^{2-}$ adduct upon anion addition, due to dissociation of the complex.¹¹ Chlorine-35 and ^{14}N NMR linewidth measurements of chloride, perchlorate, and nitrate anion binding to human Tf in a fast exchange regime allowed the determination of a 2:1 stoichiometry for V^{5+} binding to the protein, since the formation

of the ternary metal-carbonate complex at the sites determines the specific anion binding to the protein and hence leads to a decrease in quadrupolar relaxation (see *Relaxation Theory for Quadrupolar Nuclei*).⁴⁹

Proton NMR has also played an important role in the determination of the primary structure on the glycan moieties of a variety of transferrins and in the determination of solution conformation through 2D techniques.⁵⁰⁻⁵³ Studies were carried out on glycopeptides obtained by proteolytic digestion or on the intact oligosaccharide chain detached from the protein by hydrazinolysis. Readers are referred to the original literature as far as the assignment procedures are concerned. However, it is worth mentioning that recent ^1H NMR studies on Ga^{3+} binding to human Tf indicate that metal binding alters the shift of the resonances of the *N*-acetylated sugar residues of both glycan chains, suggesting that the transmission of the perturbation to the carbohydrate chains may have significance for cell receptor recognition of the metal-loaded protein.⁴⁵

3 THE ROLE OF NMR IN THE CHEMISTRY OF TRANSFERRINS: FUTURE PROSPECTS

The applicability of NMR techniques becomes less and less trivial with increase in molecular size. From this point of view, molecules of the size of transferrins represent a challenge. Multidimensional NMR, coupled with resolution enhancement techniques, of either intact and half-transferrin molecules, appear as a promising approach for detecting structural changes in the individual lobes upon metal uptake or release and ionization equilibria, and should be of use for monitoring the protein behavior toward the binding of a variety of metals and synergistic anions, under different conditions of pH and medium composition. The bottom line is to understand whether the two lobes undertake different roles in metal uptake and release processes, and whether they are functionally associated, and hence to address one of the most intriguing points of the biochemistry of transferrins related to their structural 'doubleness'. The advent of very high field spectrometers (750 MHz or higher) would greatly enhance the diagnostic power of this approach, together with the feasibility of NMR of quadrupolar metal nuclei which has proved highly sensitive to the structural features of the metal sites. The use of genetically-engineered proteins containing either amino acid substitutions, deletions, or labeled residues could also add essential information. Nitrogen-15 and/or ^{13}C selective and nonselective labeling is indeed providing a breakthrough to structural studies on medium sized proteins (see *Heteronuclear Assignment Techniques; Heteronuclear Shift Correlation Spectroscopy*).

Besides metal binding, NMR should also be a valuable means of monitoring the potential ability of transferrins to accommodate small molecules in the binding cleft.³ Overall, the application of ^1H NMR to determine protein structure in solution, coupled with molecular dynamics calculations (although the size of transferrin would set this as a long-term project) appears to be the main research direction toward the elucidation of the structure-function relationships in this class of proteins.

1 INTRODUCTION

The use of conventional NMR relaxation measurement techniques for studying moderately rapid atomic motions may result in observation of the following phenomena:

1. a decrease (or a minimum)¹ of the spin–lattice relaxation time T_1 in a plot of T_1 versus temperature;
2. motional narrowing of the resonance linewidth² (or motional lengthening of the free induction decay or the spin–spin relaxation time T_2);
3. a decrease² in the Hahn echo decay time compared to the Carr–Purcell–Meiboom–Gill (CPMG)³ time constant (see *Diffusion Measurements by Magnetic Field Gradient Methods*).

The term ultraslow motions⁴ refers to motions that are observable by NMR but are sufficiently infrequent that they produce no motional narrowing of the resonance line and make no measurable contribution to the spin–lattice relaxation rate. Typical T_1 minima correspond to motions for which the mean atomic jump rate $1/\tau_c$ is of the order of the nuclear precession frequency Ω_0 ($\approx 10^8$ s⁻¹, typically).¹ Motions having jump frequencies one or two orders of magnitude higher or lower than that for the minimum usually still give measurable contributions to the relaxation rate. Since the condition for motional narrowing is that the atomic jump time τ_c be less than T_2 , ultraslow motions are typically those for which $T_2 < \tau_c < T_1$.⁴ A very wide range of atomic motions falls under this classification, since $T_2 \approx 10^{-4}$ – 10^{-5} s in solids, while T_1 can be as long as several seconds to hours in length.

It is clearly desirable to extend to lower frequencies the frequency range (and thus the temperature range) of motions that can be studied. One advantage of studying a wider range of atomic motions is that motions having slightly different activation energies may be distinguished if they are observed over a sufficiently wide temperature range. Also, motions associated with a particular phenomenon, like a phase transition, may occur only in a particular temperature region.

The basic idea of the ultraslow motion techniques can be understood by considering what happens to a T_1 minimum if the field B_0 , and thus the resonant frequency, is greatly reduced. According to the Bloembergen, Purcell, and Pound (BPP) theory,¹ atomic diffusion or molecular reorientations

will cause fluctuations in the dipolar interactions that can be treated as perturbations on the Zeeman levels, and, furthermore, these fluctuations can be described by an exponential correlation function. BPP derived for T_1 an expression of the form

$$\frac{1}{T_1} \approx \frac{\Omega_d^2 \tau_c}{1 + \Omega_0^2 \tau_c^2} \quad (1)$$

where Ω_0 is the Larmor angular frequency and Ω_d is the angular frequency corresponding to a typical dipolar splitting. (Actually, there are additional terms of similar form. For interactions involving identical spins, there is an extra term proportional to $1/(1 + 4\Omega_0^2 \tau_c^2)$; for heteronuclear systems, there are also terms having $[1 + (\Omega_I - \Omega_S)^2 \tau_c^2]$ and $[1 + (\Omega_I + \Omega_S)^2 \tau_c^2]$ in the denominator.) Equation (1) predicts that, in a temperature plot of T_1 , there will be a minimum value for T_1 at the temperature for which $\tau_c \approx \Omega_0^{-1}$, in agreement with the idea that the transition probability $1/T_1$ arises largely from frequency components in the perturbation that equal the energy level spacing divided by $\hbar$. If Ω_0 is reduced, the minimum will correspond to a longer value of τ_c , and thus to lower frequency motions. For a typical diffusion mechanism, atomic jumps become less frequent as the temperature is lowered. Thus the T_1 minimum in a low field will occur at a lower temperature than would the T_1 minimum at a higher field.

There are experimental problems associated with attempting to study relaxation in very weak fields where the NMR signal might be very small (see *Zero Field NMR*). There are also theoretical difficulties, since the theory underlying equation (1) is a perturbation theory that treats the fluctuating dipolar Hamiltonian due to diffusion as a perturbation on the Zeeman Hamiltonian; such an assumption may not be valid in very weak applied fields. Solutions to both these problems will now be discussed. Ultraslow motion techniques have been reviewed by Ailion.^{5–7}

2 SPIN–LATTICE RELAXATION IN THE ROTATING FRAME ($T_{1\rho}$)

One approach to studying relaxation in weak applied fields and yet having the strong signal strength for a large field is to use the field cycling method^{8,9} (see *Field Cycling Experiments*), in which the external magnetic field is reduced adiabatically to a small value and subsequently increased adiabatically back to the original value, where the signal is measured. If there are no irreversible processes, the entropy will be constant, and the full signal will be measured after the remagnetization. However, atomic diffusion constitutes an irreversible process, which will cause a loss of dipolar order. Thus, by plotting the signal strength versus time in the demagnetized state, the weak field relaxation can in principle be measured. One difficulty with this approach is that it may be difficult to satisfy the requirement that the demagnetization and remagnetization processes be sufficiently slow that the adiabatic condition is satisfied and yet be rapid compared with T_1 .

An alternate approach is to measure $T_{1\rho}$, the spin–lattice relaxation time in the rotating frame of the rf field B_1 (see *Magnetization Transfer between Water and Macromolecules in Proton MRI*). According to Redfield,¹⁰ a spin system

in an rf field strong enough to saturate the resonance line (i.e., $\gamma^2 B_1^2 T_1 T_2 \gg 1$) will form a canonical distribution among energy levels separated by γB_{eff} rather than γB_0 , where the effective field B_{eff} in a frame rotating at angular frequency ω is given by

$$B_{\text{eff}} = B_1 i + (B_0 - \omega/\gamma) k \quad (2)$$

In this case, the spins will, after equilibrium has been achieved, be characterized by a ‘spin temperature in the rotating frame’, which means that Curie’s law will hold, but with $M_{\text{eq}} = CH_{\text{eff}}/T$. The significance is that, at exact resonance ($B_0 = \omega/\gamma$), the equilibrium magnetization M_{eq} will be parallel to B_1 rather than to B_0 . The $T_{1\rho}$ minimum will then occur when $\gamma B_1 \tau_c \approx 1$, for B_0 at exact resonance. Since B_1 is typically of order 1–50 G, this minimum arises from much lower frequency motions than does the normal T_1 minimum. If B_1 is much larger than the magnetic dipolar or electric quadrupolar local fields, the dipolar and quadrupolar fluctuations can still be treated by perturbation theory (this approach is called the ‘weak collision’ theory).¹¹ If, on the other hand, B_1 is comparable to or less than the dipolar or quadrupolar local fields, perturbation theory fails, and a different theory, called the ‘strong collision’ theory,¹² must be used. In this article, we shall consider the case for a spin- $\frac{1}{2}$ nucleus or one in which quadrupolar interactions can be neglected; the inclusion of quadrupolar interactions in the strong collision theory has been described by Ailion.⁵

2.1 Weak Collision Theory

All of the weak collision calculations are applications of the BPP theory in which the fluctuating dipolar Hamiltonian is treated as a perturbation on the Zeeman system. The only important difference is that the basic laboratory frame Hamiltonian is replaced by a rotating frame Hamiltonian in which B_0 is replaced by B_{eff} , as given by equation (2). At exact resonance, this theory predicts that $T_{1\rho}$ should exhibit a low-frequency minimum of the form

$$\frac{1}{T_{1\rho}} = K \frac{\tau_c}{1 + 4\Omega_1^2 \tau_c^2} \quad (3)$$

where $\Omega_1 (= \gamma B_1)$ is proportional to the energy level splitting in the rotating frame. Thus the $T_{1\rho}$ minimum occurs when $\tau_c \approx (2\Omega_1)^{-1}$, which may be several orders of magnitude longer than the value of τ_c at a typical T_1 minimum. Accordingly, a $T_{1\rho}$ minimum is deeper than a T_1 minimum, and corresponds to slower atomic motions occurring at lower temperatures, as shown in Figure 1.

2.2 Strong Collision Theory

In order to get even more effective relaxation so as to observe even lower frequency motions, B_1 , and thus Ω_1 in equation (3), can be reduced to a value comparable to the local dipolar field, or even to zero (e.g., by adiabatic demagnetization in the rotating frame (ADRF),¹³ which is discussed in Section 3.3). In this case, equation (3) would predict that the minimum would not occur unless τ_c were infinite. However, perturbation theories like BPP and the weak collision theory will not be valid, since the perturbation

Figure 1 Temperature plot of relaxation times (T_2 , T_1 , $T_{1\rho}$, and T_{1D}) and atomic jump time τ_c . (Reproduced by permission of Academic Press from D. C. Ailion, in ‘Methods of Experimental Physics’, ed. J. N. Mundy, S. J. Rothman, M. J. Fluss, and L. C. Smedskjaer, Academic Press, Orlando, 1983, Vol. 21, Chap. 6)

(the dipolar Hamiltonian) in this case is comparable to or larger than the unperturbed Hamiltonian (the Zeeman Hamiltonian). Nevertheless, the condition for the relaxation time minimum in zero magnetic field can still be easily understood. The underlying physical basis for all relaxation time minima is that the most effective relaxation (and thus the minimum) occurs when the principal frequency components of the fluctuating Hamiltonian are comparable to the energy level splitting (in units of $\hbar$). We have seen, for Zeeman relaxation in the laboratory or rotating frames, that this requirement is equivalent to requiring that $1/\tau_c \approx \Omega_0$ or $1/\tau_c \approx \Omega_1$, respectively. For relaxation due to a fluctuating dipolar Hamiltonian in zero field, the energy level splittings $\hbar\Omega_d$ are determined by dipolar interactions. Thus the minimum in zero field occurs when $1/\tau_c \approx \Omega_d$ or $\tau_c \approx T_2$, which is at the onset of motional narrowing. The zero field relaxation time for the case in which quadrupolar interactions can be neglected is commonly called the dipolar relaxation time T_{1D} ,¹⁴ and is also shown in Figure 1.

In order to study the dynamics of the atomic motions, it is desirable to obtain theoretical expressions that relate the measured relaxation time $T_{1\rho}$ or T_{1D} to the atomic jump time τ_c throughout the temperature range of observations. Experimental procedures for measuring these relaxation times are described in Sections 2.3 and 3.3, respectively. The strong collision theory, originally developed by Slichter and Ailion¹² for low-field relaxation, is not a perturbation theory, but is based on the assumption that sufficient time elapses between diffusion jumps to allow the dipolar and rotating frame Zeeman interactions to cross relax to a common spin temperature between each jump. This temperature is then disturbed by the sudden change in dipolar energy resulting from a jump, but reequilibrates in a time of order T_2 to a new value prior to the next jump. This spin temperature assumption is thus equivalent to requiring that $\tau_c \gg T_2$; hence the strong collision theory will be valid in the ‘rigid lattice’ below both the $T_{1\rho}$ minimum and the temperature for motional narrowing. If the

ADRF process is complete so that B_1 is reduced to zero in the demagnetized state, the ADRF process will have transferred long-range Zeeman order due to spins aligned preferentially along B_{eff} to short-range dipolar order from spins aligned along their individual local fields. A single diffusion jump per spin will then have a major effect on the relaxation so that, in zero B_1 , we should expect $T_{1\rho}$ ($= T_{1D}$ for zero field) to be of order τ_c . In the weak collision regime, much less of the order is dipolar and much more is Zeeman; accordingly, it will take many jumps to relax the magnetization, and $T_{1\rho}$ will be much larger than τ_c . Both these effects are shown in Figure 1.

The actual strong collision result¹² for $T_{1\rho}$ at exact resonance due to dipolar fluctuations of a homonuclear (i.e., having only one nuclear species) system in a field B_1 is

$$\frac{1}{T_{1\rho}} = \frac{1}{T_{1D}} \frac{B_D^2}{B_1^2 + B_D^2} \quad (4)$$

where B_D is the dipolar local field. We see that $T_{1\rho}$ reduces to T_{1D} in the limit as B_1 approaches zero. Note that the local field B_D can be determined experimentally by measuring $T_{1\rho}$ versus B_1^2 for fixed T_{1D} (i.e., at a fixed temperature).

2.3 Experimental Techniques for Measuring $T_{1\rho}$

Essentially all methods for measuring $T_{1\rho}$ start by tipping the magnetization from its original direction (the z direction) to a direction parallel to B_{eff} in the rotating frame, a procedure called spin locking. For exact resonance, the magnetization would then be aligned parallel to B_1 (in contrast to the situation immediately after a $\frac{1}{2}\pi$ pulse, when the magnetization would be perpendicular to B_1). $T_{1\rho}$ can then be determined by measuring the magnetization as a function of time τ in the aligned state, since $T_{1\rho}$ is given by

$$M_x = M_0 \exp(-\tau/T_{1\rho}) \quad (5)$$

where M_x is the height of the FID following the turn-off of the variable length B_1 pulse. Figure 2 shows several different pulse sequences for measuring $T_{1\rho}$.

3 DIPOLAR RELAXATION IN THE LABORATORY FRAME (T_{1D})

3.1 Homonuclear Systems

For homonuclear systems, T_{1D} can be calculated by considering the fractional change in dipolar energy per jump for N jumping atoms with a time τ_c between jumps

$$\frac{1}{T_{1D}} = \frac{N}{\tau_c} \frac{E_{Df} - E_{Di}}{E_{Di}} = \frac{N}{\tau_c} \frac{\langle \hat{\mathcal{H}}_{Df}^{(0)} \rangle - \langle \hat{\mathcal{H}}_{Di}^{(0)} \rangle}{\langle \hat{\mathcal{H}}_{Di}^{(0)} \rangle} \quad (6)$$

where E_{Di} and E_{Df} are, respectively, the dipolar energies before and after a jump. $\hat{\mathcal{H}}_{Di}^{(0)}$ and $\hat{\mathcal{H}}_{Df}^{(0)}$ are, similarly, the secular parts of the dipolar Hamiltonian (i.e., those parts that commute with the Zeeman Hamiltonian), and the angle brackets indicate expectation values. If the system can be characterized by a spin temperature before each jump, the expectation values can be expressed as traces of the quantum

Figure 2 Pulse sequences for measuring $T_{1\rho}$. (a), (b), and (c) all have a spin locking sequence followed by a long rf pulse. The spin locking in (a) consists of a $\frac{1}{2}\pi$ pulse followed by a $\frac{1}{2}\pi$ phase shift. In (b), spin locking is achieved by a π pulse about B_{eff} (at an angle of 45° with respect to the z direction). In (c), B_1 is turned on when the z field (or frequency) is far off resonance, and spin locking is achieved as a result of an adiabatic return to resonance. In (d), spin locking is achieved, as in (a), by a $\frac{1}{2}\pi$ pulse followed by a $\frac{1}{2}\pi$ phase shift; $T_{1\rho}$ is measured by monitoring the FID following short pulses of duration θ . (Reproduced with modifications by permission of Academic Press from D. C. Ailion, in 'Methods of Experimental Physics', ed. J. N. Mundy, S. J. Rothman, M. J. Fluss, and L. C. Smedskjaer, Academic Press, Orlando, 1983, Vol. 21, Chap. 6)

mechanical operators, and the following expression is obtained in the high-temperature approximation:²

$$\frac{1}{T_{1D}} = \frac{N}{\tau_c} \frac{\text{Tr}(\hat{\mathcal{H}}_{Di}^{(0)})^2 - \text{Tr}(\hat{\mathcal{H}}_{Di}^{(0)}\hat{\mathcal{H}}_{Df}^{(0)})}{\text{Tr}(\hat{\mathcal{H}}_{Di}^{(0)})^2} \quad (7)$$

This equation can be rewritten as

$$\frac{1}{T_{1D}} = \frac{2(1-p)}{\tau_c} \quad (8)$$

where $1-p$ is a calculable geometrical factor of order unity that characterizes the fractional change in energy resulting from a diffusion jump. Because of this factor, T_{1D} shows a 10–20% dependence on the orientation of the field B_0 relative to the crystal axes, and, furthermore, this anisotropy depends on diffusion mechanism.¹⁵ We also note that T_{1D} is of order τ_c , as we have seen intuitively. Diffusion can be studied by measuring either T_{1D} or $T_{1\rho}$, provided the relaxation rate due to diffusion is greater than the relaxation rate due to other T_1

processes. The condition for observability of diffusion effects is then that $\tau_c < T_1$. Since T_1 values are typically 10^{-3} – 10^3 s, this condition is much less stringent than the condition for motional narrowing ($\tau_c < T_2$).

We should note that the strong collision formula, equation (8), can be used to obtain τ_c from the measured relaxation time, assuming $\tau_c \gg T_2$. BPP-type theories can be used to determine τ_c in the motionally narrowed region where $\tau_c \ll T_2$. In the vicinity of the T_{1D} minimum, neither theory is valid.

3.2 Heteronuclear Systems

A problem arises in the interpretation of T_{1D} measurements for heteronuclear systems in which one nuclear species is diffusing and the others are stationary. For simplicity, consider a system containing two species of comparable abundance and gyromagnetic ratio, whose spin quantum numbers are labeled I and S . Assume further that the I and S spins are in strong contact. (A good example would be the alkali halide LiF, in which every lithium atom is surrounded by fluorines, and vice versa.) The problem is that if the I spins are irradiated and T_{1D} is measured, the result will be the same as when the S spins are irradiated and their T_{1D} measured, independent of which spin is actually diffusing.¹⁶ Hence, from a T_{1D} measurement alone, it would not be possible in this case to determine which species is diffusing. This feature arises because there is normally strong coupling between parts of the dipolar interaction involving different species (i.e., the I – I and S – S dipolar terms are strongly coupled through the I – S interaction). So, if an S spin undergoes a jump, there will be rapid cross relaxation between I – I and S – S terms, which will result in the local heating being transferred rapidly to the entire spin system. Thus, in the strong collision limit, the entire dipolar reservoir is describable by a single temperature prior to a diffusion jump, but either spin species alone is not.

Fortunately, there is a way to determine in a T_{1D} experiment which spin species is diffusing for the case where the S spins are weakly magnetic (small γ_S) compared with the more strongly magnetic I spins (large γ_I). If the relaxation is due to the motion of S spins, T_{1D} will have an enormous anisotropy, whereas for diffusion of I spins the anisotropy will be very small [arising only from the $1 - p$ factor in equation (8)]. A more general strong collision theory,¹⁷ appropriate for heteronuclear systems, shows that, for the case in which the strongly magnetic I spins are diffusing, only the I – I interaction terms need be kept. The resulting expression for $1/T_{1D}$ is similar to equation (8), only with p replaced by p_{II} and τ_c by τ_I :

$$\frac{1}{T_{1D}} = \frac{2(1 - p_{II})}{\tau_I} \quad (9)$$

However, if T_{1D} is due to the diffusion of weakly magnetic S spins then the diffusion produces significant changes in the I – S interaction, with the result that

$$\frac{1}{T_{1D}} = \frac{1 - p_{SI}}{\tau_S} \frac{B_{DIS}^2}{B_{DII}^2} \quad (10)$$

where B_{DIS} and B_{DII} are the I – S and I – I contributions to the dipolar local fields and τ_S is the time between jumps of the S spins. The precise definitions of these local fields and the parameters p_{II} and p_{SI} are given by Stokes and Ailion.¹⁷ equation (10) predicts a strong anisotropy, arising from the

factor B_{DIS}^2/B_{DII}^2 , which is absent for motion by I atoms. The observation of this anisotropy would confirm that the diffusion arises from the motion of weakly magnetic spins. The experimental verification of this idea is shown in Figure 7 in Section 5 below.

3.3 Experimental Techniques for Measuring T_{1D}

There are basically two commonly used methods for measuring T_{1D} , and each involves transferring order to the dipolar system and then monitoring the decrease in dipolar order arising from dipolar relaxation. The first technique consists in following a spin locking sequence by an adiabatic demagnetization–remagnetization cycle of the rf field.⁵ The second consists in creating a state of dipolar order by a pair of phase-shifted pulses and then using a third pulse to monitor the decrease in dipolar order due to the relaxation.¹⁴ Both are shown in Figure 3.

3.3.1 Adiabatic Demagnetization in the Rotating Frame (ADRF)

This method, illustrated in Figure 3(a), is similar to the methods for measuring $T_{1\rho}$, shown in Figure 2(a)–(c), except that spin locking is now followed by an adiabatic demagnetization of B_1 to zero followed a variable time later by an adiabatic remagnetization, so that the NMR signal can be measured. The adiabatic demagnetization transfers order from Zeeman order in the rotating frame to dipolar order (in alignment of the spins along the local fields). The subsequent remagnetization converts the remaining dipolar order (not destroyed by the dipolar relaxation) back to Zeeman order, where it is observed in the form of an FID following the turn-off of the rf pulse. Dipolar relaxation results in a reduction in this FID.

One limitation of this technique arises from the conflicting requirements that the B_1 sweep be adiabatic yet that it also be

Figure 3 Pulse sequences for measuring T_{1D} . (a) The ADRF sequence showing demagnetization of B_1 following spin locking. (b) The phase-shifted pulse pair sequence. The first two pulses are separated by a time that is approximately T_2 for maximum signal. (Reproduced with modifications by permission of Academic Press from D. C. Ailion, in 'Methods of Experimental Physics', ed. J. N. Mundy, S. J. Rothman, M. J. Fluss, and L. C. Smedskjaer, Academic Press, Orlando, 1983, Vol. 21, Chap. 6)

completed in a time short compared with T_{1D} . This limitation makes it difficult to measure a T_{1D} less than about 0.1–1 ms.

3.3.2 Phase-Shifted Pulse Pair

This method, shown in Figure 3(b), avoids the difficulty in measuring a short T_{1D} inherent in ADRF. In this technique, a state of dipolar order is created by applying two closely spaced pulses that are 90° out of phase. The dipolar order is observed by applying a third pulse of arbitrary phase in the (x, y) plane. The dipolar signal that appears after the third pulse is proportional to the time derivative of the FID.

A major disadvantage of this technique is that the maximum efficiency for transfer of order is only about 56%, in contrast to the 100% efficiency theoretically obtainable with ADRF.

In summary, the ADRF technique is superior when measuring longer relaxation times or when $T_{1\rho}$ measurements are also desired, while the phase-shifted pulse pair method is better for very short T_{1D} measurement.

4 DIPOLAR RELAXATION IN THE ROTATING FRAME ($T_{1D\rho}$)

The last paragraph of Section 3.2 described the possibility of using a measurement of the anisotropy of T_{1D} in a single crystal to verify that a weakly magnetic spin species is diffusing. There are two disadvantages of this approach:

1. single crystals are not always available;
2. even though S spins are diffusing, they may not be dominating T_{1D} if they are sufficiently weakly magnetic or low in abundance.

This second feature can be seen in equation (10), since, for $B_{DIS} \ll B_{DII}$, we have $T_{1D} \gg \tau_S$ for weak (S) spin motion. In contrast, for strong (I) spin motion, $T_{1D} \approx \tau_I$. These results arise from the fact that the heat capacities of the terms involving S spins are much smaller than the I – I heat capacities. Accordingly, it may be very difficult, or even impossible, in many cases to study the diffusion of sufficiently weak S spins in a T_{1D} experiment.

In order to determine the diffusing species in a slow motion experiment, it is necessary to identify a parameter that is sensitive to which species is diffusing. If this parameter can be varied by the experimenter then the diffusing species can be identified and studied. Furthermore, for the case of diffusion by spins that are so weakly magnetic as to preclude their study through direct T_{1D} measurement, it is desirable to vary the parameter so as to enhance the temperature change of the entire system resulting from the weak spins' motions. A way to perform such experiments is to observe the dipolar relaxation in the rotating frame of one of the species, say, the I spins. In this frame, only part of the original dipolar Hamiltonian will be secular. The symbol $T_{1D\rho}$ is used for the relaxation time of this secular part of the rotating-frame Hamiltonian, in analogy to T_{1D} , which is the relaxation time for the secular part of the laboratory-frame dipolar Hamiltonian. $T_{1D\rho}$ may be considered to be the dipolar relaxation time in the rotating frame, whereas T_{1D} is the dipolar relaxation time in the laboratory frame. In contrast to T_{1D} , $T_{1D\rho}$ may depend on the angle θ_I between $\mathbf{B}_{\text{eff}}$ and $\mathbf{B}_0$ in the rotating reference frame. For diffusion by the strong I spins, $T_{1D\rho} = T_{1D}$ and is described by equation (9) for all θ_I except near the magic angle θ_m (defined by $\cos^2 \theta_m = \frac{1}{3}$), where there is a

Figure 4 Pulse sequence for measuring $T_{1D\rho}$. The lower part of the figure shows the variation of $\Delta\omega_I = \gamma_I B_0 - \omega_I$, the off-resonance frequency of B_{1I} . (Reproduced with modifications by permission of the American Physical Society from H. T. Stokes and D. C. Ailion, *Phys. Rev. B*, 1978, **18**, 141)

small change.¹⁷ However, for diffusion by weak S spins, the following expression is obtained for $T_{1D\rho}$:¹⁷

$$\frac{1}{T_{1D\rho}(\theta_I)} = \frac{1}{\tau_S} \frac{\cos^2 \theta_I B_{DIS}^2 (1 - p_{SI}) + 2B_{DSS}^2 (1 - p_{SS})}{[\frac{1}{2}(3 \cos^2 \theta_I - 1)^2 B_{DII}^2 + \cos^2 \theta_I B_{DIS}^2 + B_{DSS}^2]} \quad (11)$$

where $1 - p_{SI}$ and $1 - p_{SS}$ are geometrical factors of order unity (analogous to p of the conventional strong collision theory). In contrast to the result obtained in the case of diffusion by the strong I spins, this expression predicts a very strong dependence of $T_{1D\rho}$ on θ_I , which can be observed experimentally, using the pulse sequence described in the next section.

4.1 Experimental Technique for Measuring $T_{1D\rho}$

Figure 4 shows a pulse sequence that can be used to measure $T_{1D\rho}$.¹⁷ A spin locking sequence followed by an ADRF is applied on resonance to the I spins. This step transfers Zeeman order, which was originally along $\mathbf{B}_0$, to dipolar order. A large off-resonance pulse is then applied, which does not change the dipolar order but rather changes its reference frame from the laboratory frame to the rotating frame. After establishing a spin temperature in the rotating frame, the frequency of the rf pulse is then reduced adiabatically toward resonance, thereby reducing B_{eff} and changing θ_I . By reversing this sequence, the remaining order is transferred back to laboratory-frame Zeeman order, where it appears as an FID following the turn-off of the rf pulse. If one increases the time τ in the state at θ_I , the magnitude of the resulting FID will be reduced, owing to $T_{1D\rho}$ relaxation. A plot of magnetization versus τ on a semilogarithmic plot will yield a straight line of slope $-1/T_{1D\rho}(\theta_I)$. To vary θ_I , one merely needs to vary the frequency of the pulse (and thus b_2) in the variable time interval τ .

5 EXPERIMENTAL RESULTS USING ULTRASLOW MOTION TECHNIQUES

Ultraslow motions have been widely studied in the last 30 years, generally via $T_{1\rho}$ and T_{1D} measurements. It would be impossible in this article to summarize all the applications. Instead, just a few examples will be given to confirm various

Figure 5 $T_{1\rho}$ versus reciprocal temperature in metallic lithium, with $B_1 = 1.3 \times 10^{-4}$ T. (Reproduced with modifications by permission of the American Physical Society from D. C. Ailion and, C. P. Slichter, *Phys. Rev.*, 1965, **137**, A235)

features of the previous discussion and illustrate the kinds of additional information that may be obtained from such measurements.

Figure 5 shows the original $T_{1\rho}$ data of Ailion and Slichter¹⁸ in metallic lithium. The principal feature is that the $T_{1\rho}$ minimum is symmetric and occurs at the onset of motional narrowing. Furthermore, the minimum value of $T_{1\rho}$ is within an order of magnitude of T_2 , as expected from the strong collision theory. Figure 6 shows a plot of the atomic jump time obtained from the experimental $T_{1\rho}$ values, using the strong collision theory. As can be seen, the data exhibit Arrhenius behavior over eight orders of magnitude, and correspond to extremely slow diffusion (of the order of one atomic jump per second) at the lowest temperatures.

Figure 7 shows the verification of the prediction of a very strong anisotropy in T_{1D} described in Section 3.2 for a system having diffusion dominated by weakly magnetic spins. These measurements were performed on a single crystal of KF doped with 0.1% CaF_2 . In this case, mobile potassium vacancies are created to compensate for the extra charge of the Ca^{2+} . We thus have a case in which the diffusion of weak spins (potassium) dominates T_{1D} (of fluorine). The solid curve is the calculated anisotropy of the local field factor of equation (10).

Figure 8 shows experimental verification of the strong collision theory for $T_{1D\rho}$. The sample used in this experiment is the same KF:0.1% CaF_2 single crystal used for the data of

Figure 7. The curve is calculated from equation (11). All the strong dependence of $T_{1D\rho}$ on θ_I (described earlier) appears, thereby indicating that the weak S spins (in this case, ^{39}K) are diffusing rather than the strong I spins (^{19}F here).

A possibly important potential application of this $T_{1D\rho}$ technique is the study of impurity diffusion. In this case, the S spins are weak because their concentration N_S is small (but γ_S may be large). As in the case of small γ_S , diffusion by the weak S spins should again be characterized by a sharp dip in $T_{1D\rho}$ at the magic angle. For this application to be fruitful, an abundant, easily observable I spin species must exist and be in good thermal contact with the S spins. However, it has been shown¹⁹ that nonadiabatic effects will also give rise to a dip in $T_{1D\rho}$ at the magic angle, which could mask the effect of the S spins' diffusion. Nevertheless, by appropriately modifying the 'adiabatic' sweeps of Figure 4, these effects can be minimized.¹⁹

An interesting new application of ultraslow motion NMR has been developed²⁰ to study the ultraslow hopping of selenium atoms between two sites in crystalline Se having well-resolved separate NMR lines. By selective excitation, one of the lines is saturated. Then, as the ^{77}Se atoms jump between the two sites, the magnetization of the previously saturated site builds up and the magnetization of the previously unsaturated site decreases. By measuring the time constant for these decays, the jump time τ_c and the diffusion constant D can

Figure 6 τ_c versus reciprocal temperature in metallic lithium. The experimental points were obtained from the data of Figure 5 using the strong collision theory in the low-temperature region and the weak collision theory in the high-temperature region. The 'gap' in the middle corresponds to the region around the $T_{1\rho}$ minimum where neither theory is valid. In the high temperature region, values of τ_c obtained from Holcomb and Norberg²¹ were also plotted. (Reproduced with modifications by permission of the American Physical Society from D. C. Ailion and C. P. Slichter, *Phys. Rev.*, 1965, **137**, A235)

both be directly determined. Excellent agreement was found between D measured by this NMR approach and D measured by radioactive tracers. As with the T_{1D} measurements, this technique will be able to observe jump times limited by T_1 for these specialized systems.

6 CONCLUSIONS

The most obvious advantage of the slow motion methods is to extend downward in temperature the range over which atomic diffusion can be studied. As a result, diffusion mechanisms occurring only at lower temperatures can be observed. Moreover, since the effect of diffusion on the dipolar relaxation time will be much greater than its effect on the spin-lattice relaxation time, going to zero field magnifies the relaxation effects, thereby making possible the observation of diffusion whose relaxation effects might otherwise be too weak to be observable. A measurement of the frequency dependence of the relaxation time can determine the relaxation mechanism and can check the validity of the theory used, such as the

Figure 7 T_{1D} anisotropy in KF:0.1% CaF_2 at 227°C. The crystal was rotated about its [110] axis. The curve is the calculated anisotropy of $B^2/D_{II}/B^2/D_{IS}$. (Reproduced by permission of the American Physical Society from H. T. Stokes and D. C. Ailion, *Phys. Rev. B*, 1978, **18**, 141)

assumption of an exponential correlation function, underlying equation (1). $T_{1\rho}$ and T_{1D} measurements greatly increase the frequency range available, since they are effectively very low frequency measurements (of order 10^3 Hz), in contrast to typical T_1 measurements (of order 10^7 Hz). Finally, by having a wider temperature range available, it is possible to observe the onset of other diffusion mechanisms having different activation energies. $T_{1D\rho}$ measurements can be used to enhance the NMR effects arising from the ultraslow motions of weakly magnetic nuclei and, possibly, impurities.

1 INTRODUCTION

The translational displacement of molecules in fluids and fluid-containing systems is of significance for many biological, chemical, and physical processes, encompassing phenomena such as the circulation and performance of body fluids, the functioning of living cells, the behavior of macromolecular systems, the properties of organized and ordered fluids such as thermotropic and lyotropic liquid crystals, and the permeation of fluids through porous adsorbents such as catalysts, oil reservoir rocks, etc., to mention just a few. From its earliest days NMR has developed approaches to enable these translational movements to be characterized, with a considerable degree of detail and subtlety, over spatial and temporal scales not accessed in general by other techniques. In this article we examine the ways in which NMR can be used to probe these processes, usually described as either ‘diffusion’ or ‘flow’. The use of these two terms reflects the two main driving forces for the processes: the internal thermal energy, which produces the chaotic and randomly directed diffusional displacements of molecules; and any macroscopic, usually external, constraint, such as a pressure, temperature, or density gradient, which leads to movement of fluids in a more directed and, to a greater or lesser extent, coherent manner.

Diffusion can be an important factor in determining the spin relaxation behavior in nuclear spin systems and, as such, measurements of relaxation characteristics can give information about the diffusion, albeit via indirect physical models for the relaxation process. This article, however, is concerned with NMR methods which access directly information on the translational displacements of spin-bearing molecules and ions without the requirement for such models. The principle underlying the majority of these applications of NMR to the characterization of diffusion and flow processes is very simple. It is that the spatial coordinates of spins can be distinguished and labeled by the application of magnetic field gradients. This makes the NMR frequency of the spins a function of their coordinates. Movement of the spins through this frequency-labeled space is characterized by their acquisition of phase shifts in their precession, these reflecting their frequency, and hence, their spatial coordinates’ history.

The statistics of these phase shifts reflect directly the nature of the translational displacements the spins experience. Space-labeling with field gradients is, of course, the basis of MRI and the topics covered in this article have relevance to aspects of both the power and certain limitations of MRI. The reader is referred to the many articles on this topic contained in this Encyclopedia.

In order for the statistics of the phase shifts, and hence translational displacements, mentioned above to be measured, the spins have to have a collective phase coherence imposed on them to start with, rather like runners being called to the starting line on a race track. It was in this context that in 1950 Hahn¹ described for the first time the formation of spin echoes, through the application of two or more rf pulses to a spin system in an inhomogeneous magnetic field, and discussed, inter alia, the effects of diffusion through this inhomogeneous field on the echo formation. Subsequently, Carr and Purcell² derived in more detail the expression for the effect of self-diffusion on spin echo formation in the presence of an applied linear field gradient, demonstrated the measurement of self-diffusion coefficients using this phenomenon, and established the effects of convection, which is a flow process in our terms, on both single and multiple echo formation. These two papers form the foundations on which all that follows rests.

A second type of space labeling involves saturation of longitudinal magnetization which, coupled with time-of-flight/MRI methods of observation, can also be used for the characterization of diffusion and flow processes. These are not covered in this article, but can be accessed through the reviews cited.

2 SPIN ECHOES IN THE PRESENCE OF MAGNETIC FIELD GRADIENTS

The early work referred to above considered the effects of diffusion and flow in the presence of a time-independent magnetic field gradient. In practice, it turns out to be advantageous from a number of standpoints to apply the gradient in the form of pulses, usually rectangular. Figure 1 illustrates the simplest form of the experiment used to study diffusion and flow.

This pulsed gradient spin echo (PGSE) experiment comprises a $90^\circ_x - \tau - 180^\circ_y - \tau$ echo sequence with two identical field gradient pulses (FGP) applied. These have duration δ , amplitude $|g|$, and are separated by a time Δ . Also shown is a steady gradient g_0 . In many situations such a steady gradient is unavoidable arising, for example, from inhomogeneities in the B_0 field or from internal inhomogeneities in the sample. The applied gradient g and the steady gradient g_0 are not necessarily colinear. Indeed, there may be a distribution of angles between them if g_0 has a distribution of directions. In general, applied gradients are taken as linear, i.e. for $g_x = \{\delta B/\delta x\}$:

$$\omega(x) = \gamma B(x) = \gamma B_0 + \gamma g_x x \quad (1)$$

where γ is the magnetogyric ratio of the spins. Note that the term ‘gradient’ means the spatial derivatives of the static field B_0 .

Figure 1 The basic pulsed magnetic field gradient spin echo experiment, comprising a 90° – τ – 180° spin echo sequence with two FGPs superimposed. The first FGP labels the position of spins in the gradient direction through phase shifts which cause the loss of signal at around t_1 . The second FGP, together with the 180° rf pulse, refocuses these phase shifts and regenerates a signal which reflects the degree to which spins have moved to different positions in the gradient direction during the time Δ . The imbalance in FGP width shown as ϵ is important in considering the experimental behavior (see Section 2.3)

2.1 Phase Shifts and Translational Displacements

The PGSE experiment was first analyzed and demonstrated experimentally by Stejskal and Tanner.^{3,4} Whilst there have been a number of approaches to analyzing the response of spin echo experiments to translational motions of the spins, here a simple approach will be followed initially, concentrating on the effects of the FGPs only. This gives a particularly clear physical picture.

The assumption is made that the FGPs are of negligible duration with regard to the movements of the spins along the gradient direction. In practice this means it is assumed that spins remain fixed in their positions during the FGPs. The 90°_x rf pulse (see Figure 1) creates the required initial phase coherence in the spin system. The natural decay timescale of this coherence, the transverse relaxation time T_2 , sets the limit for the time available in this particular experiment for the observation of the translational movements. In addition, the formation of an echo, as illustrated, arises from the refocusing by the 180°_y rf pulse of the dephasing of the FID due, inter alia, to the effects of g_0 .

Neglecting these relaxation processes for the moment, the first FGP gives to the spins phase shifts proportional to their position in the gradient direction at that time (taken as the origin of time, i.e. $\Delta = 0$, for the characterization of the translational motions), e.g. for the i th spin with position $x_i(0)$ at the time of application of the first FGP,

$$\phi_i(0) = \gamma \delta g_x x_i(0) \quad (2)$$

The spins are now labeled in terms of their x coordinate at $\Delta = 0$ through this phase shift. The effect of the 180°_y rf pulse is to make the second FGP, applied a time Δ after the first, act

as if it were of reverse polarity, i.e. $-g_x$. (NB: The experiment could be carried out using only two, opposite polarity, FGPs without the 180°_y rf pulse.) Following this, the i th spin has the resultant phase shift

$$\phi_i(\Delta) = \gamma \delta g_x [x_i(\Delta) - x_i(0)] = \gamma \delta g_x X_i(\Delta) \quad (3)$$

What is clear from equation (3) is that if all spins have not changed their x coordinates in the time Δ [i.e. $X_i(\Delta) = 0$ for all i], they all have no net phase shift and the coherence, apparently destroyed by the first FGP [i.e. the NMR signal will have disappeared at this point (see Figure 1)], is recovered. If the spins have experienced finite displacements in the time Δ , then each contributes to the NMR signal following the second FGP by the amount

$$s_i(g_x, \delta, \Delta) = \exp[i\phi_i(\Delta)] = [\cos \phi_i(\Delta) + i \sin \phi_i(\Delta)] \quad (4)$$

where the real and imaginary components correspond to the y and x components of the magnetization in the rotating frame defined by the x/y rf pulses. The total NMR signal following the second FGP is then the sum over all the spins:

$$S(g_x, \delta, \Delta) = \sum_i s_i(g_x, \delta, \Delta) = \langle \exp[i\phi(\Delta)] \rangle \quad (5)$$

where $\langle \dots \rangle$ represents an ensemble average.

Clearly, the result of equation (5) depends on the statistics of the displacements $X_i(\Delta)$. For example, in the simplest possible case in which all spins experience the same displacement (this would represent ‘plug flow’) the NMR signal would be recovered unchanged in amplitude, as all the spins would be in phase immediately after the second FGP, but would be phase shifted by an amount

$$\phi^{\text{PF}}(\Delta) = \gamma \delta g_x X^{\text{PF}}(\Delta) = \gamma \delta g_x \Delta v \quad (6)$$

where the superscript PF designates plug flow, and v is the velocity in the gradient direction.

For this case the full NMR signal behaves according to equation (4) with ϕ^{PF} given by equation (6). In general, however, the molecules carrying the spins experience a distribution of displacements $P[X_i(\Delta)]$ during the observation time Δ . This, in turn, results in a distribution of phase shifts $P[\phi(\Delta)]$ and an NMR signal which has the form

$$S(g_x, \delta, \Delta) = \int P[\phi(\Delta)] \exp[i\phi(\Delta)] d\phi \quad (7)$$

which may be expressed as

$$S(g_x, \delta, \Delta) = \int dx_0 \int dx P(x_0) P(x, \Delta; x_0) \times \exp[i\gamma \delta g_x [x(\Delta) - x_0]] \quad (8)$$

or, more generally,

$$S(\mathbf{q}, \Delta) = \int d\mathbf{r}_0 \int d\mathbf{r} P(\mathbf{r}_0) P(\mathbf{r}, \Delta; \mathbf{r}_0) \times \exp[i2\pi \mathbf{q} \cdot (\mathbf{r} - \mathbf{r}_0)] \quad (9)$$

where $\mathbf{q} = (2\pi)^{-1} \gamma \delta \mathbf{g}$ and $P(x, \Delta; x_0)$ and $P(\mathbf{r}, \Delta; \mathbf{r}_0)$ are the conditional probabilities for displacements $(x - x_0)$ and $(\mathbf{r} - \mathbf{r}_0)$, respectively, in time Δ ; i.e. the probability that, given a starting position x_0 or $\mathbf{r}_0$, spins will reach position x or $\mathbf{r}$ in time Δ . As, in general, these conditional probabilities can depend on the starting position, they must be treated as functions of these, hence the integration over the probability density for starting positions, $P(x_0)$ or $P(\mathbf{r}_0)$. These latter terms are merely the spatial spin density distributions.

Equation (9) may also be written in terms of what Kärger and Heink⁵ called the ‘average propagator’, $\langle P[X(\Delta)] \rangle$, i.e.

$$S(q, \Delta) = \int \langle P[X(\Delta)] \rangle \exp[i2\pi q X(\Delta)] dX \quad (10)$$

where the average propagator is given by

$$\langle P[X(\Delta)] \rangle = \int P(x, \Delta; x_0) P(x_0) dx_0 \quad (11)$$

and $q = |\mathbf{q}|$.

Equation (10) shows that $S(q, \Delta)$ and $\langle P[X(\Delta)] \rangle$ are a Fourier pair and that determination of $S_\Delta(q)$ (i.e. the q dependence of the NMR signal at fixed observation time Δ) allows the direct measurement of $\langle P[X(\Delta)] \rangle$ by Fourier transformation of $S_\Delta(q)$ with respect to q .

The definition of $\mathbf{q}$ (note that it has dimensions of inverse distance) and its role in equations (9) and (10) is analogous to that of a wavevector in diffraction and scattering phenomena. This viewpoint is described by Callaghan⁶ in his review of this field and has recently found more favor through the application of these NMR methods to the diffusion of fluids in porous solids.⁷⁻⁹

2.2 Unrestricted Self-Diffusion and the PGSE Experiment

Self-diffusion is the translational displacement of molecules driven by internal kinetic energy. It is chaotic and random in character and can be thought of in terms of a random walk process. The statistics of displacements for such a random walk are Gaussian, i.e. in one dimension,

$$P[X(\Delta)] = (4\pi D\Delta)^{-1/2} \exp[-X(\Delta)^2/4D\Delta] \quad (12)$$

where D is the self-diffusion coefficient. Equation (12) provides a phenomenological definition of D through the mean squared displacement:

$$\langle X^2(\Delta) \rangle = nD\Delta \quad (13)$$

($n = 2, 4$, or 6 for one, two, or three dimensions) and is a solution of Fick’s diffusion equation:

$$dP/dt = D(d^2P/dx^2) \quad (14)$$

A statistical mechanical definition of D is through the velocity correlation function

$$D = \int_0^\infty \langle v(t) \cdot v(0) \rangle dt \quad (15)$$

A detailed discussion of the relationship between self-diffusion and the mutual diffusion coefficient in a binary system is given by Mills et al.¹⁰

Equation (12) is valid under the condition that $\Delta \ll L^2/D$, where L is the size scale separating any barriers to the free diffusion process.⁹ Under these conditions the diffusion is described as ‘unrestricted’.

For the PGSE experiment, the substitution of equation (12) into equation (8) gives

$$S(q, \Delta) = S_0 \exp(-4\pi^2 q^2 \Delta D) \quad (16)$$

where S_0 is the NMR signal measured in the absence of the FGPs. In general, because the background gradients cause echo formation around 2τ , it is normal to measure the echo amplitude at this time, with and without the gradient pulses applied, in which case $S_0 = S(2\tau)$. The role of the background gradients is important and is discussed below. If the PGSE experiment is carried out under high-resolution conditions (i.e. the effects of background gradients are eliminated) then the signal $S(q, \Delta, t)$, where t runs from 2τ onwards, may be measured and Fourier transformed with respect to t to give a high-resolution spectrum in which each resolved peak suffers attenuation according to equation (16), with a value of D appropriate to the molecular species. This area has been reviewed by Stilbs.¹¹

Equation (16) is based on equation (8), which assumes no movement of the spins during the FGPs. This is equivalent to $\Delta \gg \delta$. If this is not the case, a more general treatment shows that the exact result is

$$S(q, \Delta) = S_0 \exp[-4\pi^2 q^2 (\Delta - \delta/3)] \quad (17)$$

In the limit when $\Delta = \delta = \tau$, i.e. the case when there is a constant gradient present throughout the spin echo experiment, equation (17) becomes

$$S(g, \tau) = S_0 \exp(-2\gamma^2 g^2 \tau^3/3) \quad (18)$$

This is the original equation derived by Hahn¹ and Carr and Purcell.²

Equations (16)–(18) form the basis for the measurement of the self-diffusion coefficients of spin-bearing molecules. The spin echo amplitude is determined as a function of the FGP parameters q and Δ , and a fit to the appropriate equation (given that g is known) gives D . An example of a typical set of data for simple fluids is shown in Figure 2. The range of D accessible to measurement depends on the nucleus used, the spin relaxation properties of the system, and the FGP amplitude/width capability of the spectrometer. In general, it is relatively straightforward to measure D for fairly mobile liquids ($D \geq 10^{-10} \text{ m}^2 \text{ s}^{-1}$). However, for systems with higher viscosities the difficulties in determining D multiply. This is because, as D becomes smaller, T_2 tends to get smaller, which means that to generate a given attenuation of the echo signal more gradient area is required but with less time in which to apply it. Gradient amplitudes of the order of 10 T m^{-1} or more can be generated but require specialized design of coils, current sources, etc. Aspects of these experimental issues are mentioned later. Values of D of the order of 10^{-11} to $10^{-12} \text{ m}^2 \text{ s}^{-1}$ can be measured without too much difficulty. Smaller values offer increased

Figure 2 Typical PGSE echo signal decays used to determine the self-diffusion coefficients of the constituents benzene and butanol. The data are plotted as a function of $I^2 \delta^2 \Delta$ with the current I proportional to g . The diffusion coefficients are obtained from the slope of the lines according to equation (16). (Reproduced by permission of CSIRO from P. T. Callaghan, *Aust. J. Phys.*, 1984, **37**, 359)

experimental challenges, with values as low as $10^{-14} \text{ m}^2 \text{ s}^{-1}$ probably representing the limit. Use of nuclei other than protons is possible, although the dependence of the echo attenuation on γ^2 implies a considerable penalty. For ^{13}C , for example, this requires an increase of a factor of 4 in the FGP area to maintain the same echo attenuation compared with a measurement using ^1H with the same diffusion coefficient. Use of multiple quantum coherences can be partly successful in regaining the sensitivity,¹² as a coherence of order n has an effective precession frequency of $n\omega_0$.

The accuracy of the determination of D again depends on a number of factors.¹³ Perhaps most critical is whether g is determined directly, in which case this is usually the limiting factor, or whether g is calibrated through use of a sample of known D , determined by another method. Linearity and stability of the gradient generation system and the rf amplifiers and detectors can also play an important role in limiting accuracy and precision (see Section 2.3).

2.3 Finite Width FGPs and Effects of Background Gradients

Equations (8) and (9) are valid in the limit $\delta \rightarrow 0$ with $g\delta$ remaining finite, or, in a practical sense, when evolution of $P(x, \Delta; x_0)$ during δ is negligible. To calculate the response of the PGSE and other pulse sequences when these conditions are not satisfied requires that the phase shifts of the spins

are calculated by integration over their gradient/coordinate histories:

$$\phi_i(t) = \int \Omega_i(t') dt' \quad (19)$$

where $\Omega_i(t') = [\omega_i(t') - \omega_0]$.

One approach to the solution of this problem was that used by Douglass and McCall¹⁴ for the case of a constant gradient. This was also used by Neuman¹⁵ and Murday and Cotts¹⁶ for restricted diffusion (see Section 3.1). The essence of this approach is the assumption that the phase probability distribution $P[\phi(\Delta)]$ [see equation (7)] is Gaussian for all Δ . This gives the spin echo amplitude as

$$S(2\tau) = S_0 \exp[-\langle \phi^2(2\tau) \rangle / 2] \quad (20)$$

where

$$\begin{aligned} \langle \phi^2(2\tau) \rangle = \gamma^2 g_0^2 & \left[\int_0^\tau dt \int_0^\tau dt' - 2 \int_0^\tau dt \int_\tau^{2\tau} dt' \right. \\ & \left. + \int_\tau^{2\tau} dt \int_\tau^{2\tau} dt' \right] \langle x(t)x(t') \rangle \end{aligned} \quad (21)$$

and where the position correlation function has the general form¹⁵

$$\begin{aligned} \langle x(t)x(t') \rangle = \int d\mathbf{r}_0 \int d\mathbf{r} \int d\mathbf{r}' & (\mathbf{r} - \mathbf{r}_0)_x (\mathbf{r}' - \mathbf{r}_0)_x P(\mathbf{r}_0) \\ & \times P(\mathbf{r}, t; \mathbf{r}_0) P(\mathbf{r}', t' - t; \mathbf{r}) \end{aligned} \quad (22)$$

in which the $P(\mathbf{r}, t; \mathbf{r}')$, etc., are the usual conditional probabilities. For unbounded self-diffusion this leads directly to equation (18). Recently, the question concerning the generality of the assumption of Gaussian character for $P[\phi(t)]$ for restricted diffusion¹⁵ has been investigated for the case of plane parallel and spherical barriers (see Section 3.1).

An alternative approach, used by Stejskal and Tanner,^{3,4} starts with addition of a diffusion term to the Bloch equation describing the time dependence of the transverse magnetization:

$$dM/dt = [i\omega_0 - (1/T_2) - i\gamma(\mathbf{r} \cdot \mathbf{g}) - D\nabla^2]M \quad (23)$$

The contribution of diffusion is emphasized by defining ψ as

$$\psi = M \exp[-i\omega_0 t + (1/T_2)t] = A(t) \exp(-i\gamma \mathbf{r} \cdot \mathbf{F}) \quad (24)$$

where

$$\mathbf{F}(t) = \int \mathbf{g}(t') dt' \quad (25)$$

and the effects of diffusion are contained in $A(t)$ through

$$dA(t)/dt = -\gamma^2 D [\mathbf{F} + (\xi - 1)\mathbf{f}]^2 A \quad (26)$$

in which $\xi = -1$ for $t > \tau$ and $+1$ for $t < \tau$. For the sequence in Figure 1, $f = F(\tau)$. The echo amplitude at 2τ for this sequence is given by

$$\begin{aligned} \ln[A(2\tau)/A(0)] = & -\gamma^2 D \{ 2\tau^3 g_0^2/3 + \delta^2(\Delta - \delta/3)g^2 \\ & -\delta[(t_1^2 + t_2^2) + \delta(t_1 + t_2) + 2\delta^2/3 \\ & + 2\tau^2]g \cdot g_0 \} \end{aligned} \quad (27)$$

As indicated above, the presence of a steady field gradient g_0 is almost inevitable, except for homogeneous liquid samples studied using a high-resolution spectrometer.¹¹ Such ‘background’ gradients can arise from intrinsic inhomogeneity in the applied static field, may be generated deliberately by passing a steady current through the coils used to apply the pulsed gradients or coils used to shim the main field, or may be induced within the sample if this has significant spatial variations in its magnetic susceptibility. In probing the translational displacements of spins using the PGSE experiments, account must generally be taken of the interplay between g and g_0 , whether the aim is to extract accurate transport coefficients [e.g. using equation (27)], to minimize the impact of g_0 , or to exploit it. A detailed analysis of the role of g_0 on PFG experiments has been presented by Hrovat and Wade,¹⁷ whilst Williams et al.¹⁸ and Karlicek and Lowe¹⁹ have devised pulse sequences which aim to remove the effects of diffusion through g_0 whilst discriminating in favor of the effects of the applied FGPs (see below). These have been further developed by Latour et al.²⁰

A feature of the PGSE experiment is that the amplitudes and time of occurrence of the spin echo maxima can show variability, although careful attention to equipment design can reduce these considerably.²¹ This sensitivity can be understood in qualitative terms by recognizing that, even for a modest FGP amplitude and a sample with dimensions of the order of 1 cm, the difference in phase produced at either side of the sample by a typical FGP can be several thousand radians. The second FGP must be capable of refocusing shifts of this order such that the full signal is recovered to certainly better than 1% or so. This requires very careful balancing of the two (or more) FGPs and, as already indicated, careful attention to apparatus design and construction.

Understanding the effects of imbalance in the gradient pulses is important and, using similar terminology to that in equation (24)–(27), Hrovat and Wade¹⁷ have described the effects of this imbalance in the length of the FGPs. This imbalance, shown in Figure 1 as an extra width ϵ in the second FGP, leads to a reduction in the amplitude of the echo and a shift in the time of the echo maximum t_e from 2τ . Typically, for a cylindrical sample of radius R , with the gradient applied perpendicular to the cylinder axis, the echo amplitude at the maximum ($t = t_e$) is given by

$$S(t_e) = 2J_1(\gamma R g \epsilon \sin \alpha) / \gamma R g \epsilon \sin \alpha \quad (28)$$

where J_1 is the first-order Bessel function, and α is the angle between g_0 and g . This shows that even small imbalances in the two FGPs can give significant amplitude reductions, quite unrelated to diffusion. Similarly, the shift of t_e from 2τ is found to be $g \epsilon \cos \alpha / g_0$. In general, the FGPs are balanced empirically and the criterion which should be used is found to

Figure 3 (a) The simplest of the alternating gradient multiple pulse sequences devised by Karlicek and Lowe¹⁹ to allow the measurement of diffusion processes in systems with significant internal magnetic field gradients. (b) The effective polarity of the four FGPs applied during this sequence. The effect of the background gradients is reduced through the effects of the multiple echo formation

be maximizing the echo intensity rather than forcing t_e as close as possible to 2τ . It is also found, consistent with experimental observation, that the presence of a significant g_0 parallel to g produces a stabilization of the position of the echo when its width is dominated by g_0 .

Figure 3(a) shows the simplest of the alternating PFG spin echo experiments devised by Karlicek and Lowe¹⁹ to allow the measurement of diffusion coefficients in materials which have strong internal steady field gradients.

It is a CPMG-type multiple echo sequence involving five 180° pulses. As mentioned above, the effect of a 180° pulse is effectively to reverse the polarity of a following FGP relative to that before it. The applied FGPs in this sequence alternate in sign with a mirror reflection at the central 180° pulse. As the switching in polarity occurs at each 180° pulse the net effect is to produce the equivalent of a bipolar applied FGP [Figure 3(b)] which then produces a full effect in terms of diffusional attenuation of the final echo. The effect of the multiple echo sequence on the internal (or background) gradient, however, is to reduce its effectiveness (see Section 2.4) and also to remove the $g \cdot g_0$ contribution of equation (27).

2.4 The Stimulated Echo and Other Alternative Pulse Sequences

The Karlicek and Lowe sequence, mentioned above, makes use of the fact that, inter alia, diffusion through existing gradients in the sample can be discriminated against by use of a multiple echo sequence. In fact Carr and Purcell² showed that the echo at time $t = 2n\tau$ in their $90^\circ - \tau - (180^\circ - 2\tau -)$

Figure 4 The pulsed gradient stimulated echo (PGSTE) sequence used to study diffusion and flow. It is particularly useful in systems where $T_1 \gg T_2$. During the time T the signal which gives rise to the stimulated echo relaxes at a rate determined by T_1 , which allows Δ to be made larger than for the corresponding PGSE experiment for the condition $T_1 \gg T_2$

sequence in the presence of a static field gradient g_0 was

$$S(t = 2n\tau) = S(0) \exp[-(1/T_2 + \gamma^2 g_0^2 D \tau^2 t/3)] \quad (29)$$

which indicates that if the pulse separation is made small enough the effects of diffusion through the gradient may be eliminated. If combined with applied FGPs, this rf pulse sequence can be thought of as modifying the intrinsic relaxation properties of the sample (in this case produced by internally generated gradients) in order to allow the controlled use of the PFG approach with maximum time for observation of the diffusional displacements, i.e. T_2 as compared with T_2^* (or something close to this). In fact many possibilities exist for using the variety of rf pulse sequences which allow different relaxation behaviors to determine the timescales over which the translational displacements may be observed. Probably the most used of such alternative sequences is the stimulated echo (STE) sequence which is shown in its PFG version in Figure 4.

The use of this for diffusion measurements was first suggested and demonstrated by Tanner.²² The essence of the STE sequence, originally discussed by Hahn,¹ is that in a general three-rf-pulse sequence five echoes are produced. Of these, that occurring at a time τ following the third pulse, i.e. $t = (T + 2\tau)$ in Figure 4 is the important echo for the purposes of diffusion and flow studies. It is known as the stimulated echo and arises from magnetization which is stored in the longitudinal (B_0) direction in the period between the second and third rf pulses. In terms of relaxation its amplitude is given by

$$S(T + 2\tau) = [S(0)/2] \exp[-(2\tau/T_2 + T/T_1)] \quad (30)$$

which means that, for systems in which $T_1 \gg T_2$, it can be advantageous to use this sequence despite the fact that the STE has a maximum intensity only half that of the normal spin echo in Figure 1. The attenuation of the pulsed gradient stimulated echo (PGSTE) arising from diffusion has the form

$$S(T + 2\tau) = 0.5S(0) \exp[-\gamma^2 g^2 \delta^2 D(\Delta - \delta/3)] \quad (31)$$

but with the accessible range of Δ now being determined in the main by T_1 , particularly when $T_1 \gg T_2$. The choice of when to use the PGSTE or other pulse sequences rather than the simple PGSE method is dictated by the nature of the spin

relaxation characteristics of the sample under study. A fuller discussion of the use of the STE and other pulse sequences for the study of diffusion may be found in Section V of the review by Kärger et al.²³

3 HINDERED, ANISOTROPIC, AND RESTRICTED DIFFUSION

In Section 2, discussion of diffusion was limited to a Gaussian propagator, i.e. equation (12) for which the mean squared displacement increases linearly with time Δ [equation (13)]. The power of the PGSE method is that, through the dependence of the NMR signal on q and Δ , it provides a means of probing the translational propagator over a range of spatial and temporal scales. The accessible ranges of these scales in any material are determined by, on the one hand, the intrinsic diffusion coefficients and the spin relaxation characteristics (the latter constraining the range of Δ) and, on the other, the values of q achievable—usually dictated by instrumental design characteristics.

In homogeneous solutions of small molecules of generally similar size, any deviations from Gaussian behavior of the propagator are dissipated on a distance scale for displacements which are of the order of a molecular diameter d , and hence on timescales of the order of (d^2/D) , which will be nanoseconds or less. As discussed by Callaghan and Coy²⁴ this is the province of neutron scattering. On the other hand, for small molecules diffusing through systems which have structural features or obstacles to diffusion of the order of micrometers, timescales are of the order of milliseconds and this brings such effects within the normal range of the PGSE and related experiments. Typically, Δ can cover the range 0.1–1000 ms, corresponding to mean squared displacements in mobile fluids in the range 0.5–50 μm .

The use of the terms ‘hindered’ and ‘restricted’ in the heading of this section is intended to draw a qualitative distinction between two limiting situations. Restricted diffusion is usually taken to be that in which the molecular translational displacements are constrained by impermeable barriers to remain trapped within finite regions of space, these regions being of a size such that the diffusing molecules may encounter and be reflected by the barriers within the timescale Δ . ‘Hindered’ is not a widely employed term, but is one which might be used to describe those situations in which the mean squared displacement of the diffusing molecules is not bounded but, nonetheless, suffers a change in its effective rate of change over the timescale Δ . In reality, there is a continuity of behavior from restricted through to completely free diffusion. The term ‘anisotropic’ is self-explanatory—the diffusion occurs at different rates in different directions in space. These spatial directions are usually defined within the material under study by its structure and organization. There may be a distribution of orientations of these internal features with respect to the applied field gradient direction.

Before introducing certain quantitative descriptions of these restricted non-Gaussian diffusion effects, it is helpful to consider, qualitatively, a simple model with the aims of discriminating the roles of q and Δ and of illustrating the general behavior of the PGSE NMR signal in the presence of such effects. Figure 5 shows molecules diffusing between

Figure 5 A typical trajectory of a spin undergoing diffusion between plane parallel impenetrable barriers showing reflection at the barrier. Also shown is the general behavior of the propagator for displacements for a spin starting at x_0 . It is clear that the propagator will be a function of starting position with spins starting near the walls experiencing their effect sooner and to a greater extent in that earlier period than those starting further away

two parallel planar and impermeable barriers, separated by a distance $2L$. The PFG $\mathbf{g}$, and hence $\mathbf{q}$, is taken as being perpendicular to the planes. Molecules starting at x_0 explore the surrounding space. The propagator $P(x, \Delta; x_0)$, representing an average over all possible trajectories, evolves in a Gaussian fashion until it encounters the barrier which reflects it back into the space between the barriers. It is clear immediately that the behavior of the propagator is a function of starting position x_0 . At times Δ such that $(2D\Delta)^{1/2} \ll (L - x_0)$ spins starting at x_0 diffuse without being influenced significantly by the barriers, and the echo signal obeys equation (16) to a good approximation. The smaller $(L - x_0)$, the sooner (on average) the spins experience the effects of the constraining barriers. Indeed, in the limit of low $\mathbf{q}$ (defined by $qL \ll 1$), the short-time behavior of such a system has been shown^{25,26} to be consistent with the result

$$[D_{\text{eff}}(\Delta)/D(0)] = 1 - (4/9\sqrt{\pi})(S/V)D^{1/2}\Delta^{1/2} + \text{higher terms} \quad (32)$$

where $D_{\text{eff}}(\Delta)$ is obtained from the variation with q of the signal at fixed Δ according to

$$S_{\Delta}(q) = S_{\Delta}(0) \exp[-4\pi^2 q^2 \Delta D_{\text{eff}}(\Delta)] \quad (33)$$

and where S/V is the surface-to-volume ratio of the obstacles to diffusion.

In the limit of long observation times ($\Delta \geq L^2/D$) all spins, regardless of their x_0 value, encounter the barriers and, for each x_0 , the propagator tends to the spin density function $P(x_0)$:

$$P(x, \infty; x_0) \rightarrow P(x_0) \quad (34)$$

This makes the average propagator the autocorrelation function of the spin density:

$$\langle P[X(\infty)] \rangle = \int P(x_0 + X)P(x_0) dx_0 \quad (35)$$

The Wiener-Khinchine theorem²⁷ shows that the Fourier transform of an autocorrelation function of a property is the power spectrum of that property and, since $S(q, \Delta)$ is the q -space Fourier transform of the average propagator, this means that for this planar barrier model

$$S(q, \infty) = |\text{sinc}(\pi qL/2)|^2 = |I(q)|^2 \quad (36)$$

where

$$I(q) = \int P(x_0) \exp(i2\pi qx_0) dx_0 \quad (37)$$

which is the same quantity measured in conventional NMR imaging. As was first pointed out by Cory and Garroway,²⁸ this behavior is analogous to the optical intensity diffraction pattern arising from a single slit of width $2L$.

This discussion leads to a general understanding of the roles of Δ and $\mathbf{q}$ in the PGSE experiment for situations in which diffusion occurs through systems which impose some spatially distributed obstacles or barriers. To access information dominated by diffusive motion, the condition $qL \ll 1$ must be approached in general. For short observation times Δ it can be shown²⁴ that the PGSE response has the form

$$S(\Delta, q \ll L^{-1}) \approx 1 - (1/2!)(2\pi q)^2 \langle X^2(\Delta) \rangle + \dots \quad (38)$$

where $\langle X^2(\Delta) \rangle$ is the mean squared displacement at time Δ .

For a system which has obstacles to diffusion on a spatial scale L , measurements when $\Delta < L^2/D$ with $qL \ll 1$, will give a diffusivity which tends to that of the bulk fluid together with information on the surface-to-volume ratio of the obstacles [equation (32)]. For $\Delta \geq L^2/D$, on the other hand (with $qL \ll 1$ still), the diffusivity measured increasingly incorporates the influence of the obstacles.

Varying q such that $qL \geq 1$ probes the structural arrangement and features of the obstacles, as seen by the displacements $X(\Delta)$. So, for $\Delta \ll L^2/D$, the q dependence will be weak, since few spins have encountered the effects of the obstacles, whereas once $\Delta \geq L^2/D$ varying q such that $qL \geq 1$ imposes strong structure-related behavior on the PGSE signal. For structures with some periodicity or local order this can have the form of diffraction-like effects with coherences appearing when $qL \approx \text{integer}$ (see Section 3.2). Figure 6 gives an example of such behavior. It is interesting to realize that, despite the long history of this experiment and the obvious similarity of its mathematical formulation to diffraction and

Figure 6 The spin echo amplitude $S_{\Delta}(q)$ as a function of q for protons in liquid pentane diffusing in a structure made up of rectangular microcapillaries with a separation of approximately $100 \mu\text{m}$. $\Delta = 950 \text{ ms}$. The diffraction-like effects are clearly visible. The solid line is a fit to equation (39) which gives $2L = 107 \mu\text{m}$ and $D = 5 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ (see Figure 5). (Reproduced by permission of Kluwer from Callaghan and Coy in *NMR Probes of Molecular Dynamics*, ed. R. Tycko, Dordrecht, 1994)

scattering phenomena in general, it was only recently recognized and demonstrated^{7,8,28} that an essentially dissipative process, i.e. self-diffusion, could result in the growth of an NMR coherence as well as the usually expected decay.

3.1 Restricted Diffusion

The general problem of calculating the echo response for restricted diffusion has been approached in a number of ways. In general, solutions have to be found for the diffusion equation with the appropriate boundary conditions and these solutions used to calculate the phase shift distributions of spins in the applied gradient. The results for the plane parallel barrier case will be used as an example. Full details of other geometries and models can be found in the many excellent reviews.^{4,6,11,23,24,29}

The echo attenuation arising from diffusion in the plane parallel barrier case of Figure 5 was first analyzed by Stejskal and Tanner.³⁰ The general result has the form:

$$S(q, \Delta) = (\text{sinc } 2\pi qL)^2 + (8\pi qL)^2 \sum_{n=1}^{\infty} \exp(-n^2\pi^2 D\Delta/4L^2) \times \{[1 - (-1)^n \cos(4\pi qL)] / [(4\pi qL)^2 - (n\pi)^2]^2\} \quad (39)$$

In the short- and long-time limits ($\Delta \ll 4L^2/D$ and $\Delta \gg 4L^2/D$) equation (39) reduces, as expected, to equation (16) and equation (36), respectively. Figure 7 illustrates the general behavior of equation (39) in terms of the mean squared displacement $\langle X^2(\Delta) \rangle$ and the variation of $D_{\text{eff}}(\Delta)$ with Δ for the plane parallel barrier case shown in Figure 5.

Figure 7(a) shows that for $\Delta D < 4L^2$, $\langle X^2(\Delta) \rangle$ increases linearly with Δ but when $\Delta D > 4L^2$ it tends to a limit of $2L^2/3$. The value of D_{eff} undergoes a transition from D to $L^2/3\Delta$, as illustrated in Figure 7(b). A typical set of experimental

Figure 7 Mean squared displacement and effective diffusion coefficient for spins diffusing between planar parallel impenetrable barriers of separation $2L$. (Adapted and reproduced by permission of Academic Press Ltd. from J. Kärger, H. Pfeifer and W. Heink, *Adv. Magn. Reson.*, 1988, **12**, 1)

Figure 8 A typical set of echo attenuation data for restricted diffusion in an emulsion. The data are plotted as a function of observation time Δ for different gradient intensities q . This shows the change of effective diffusion coefficient with both these variables. The lines are fits to theoretical expressions for diffusion in spherical containers with a log-normal distribution of diameters. (Adapted and reproduced by permission of Academic Press Inc., from K. J. Packer and C. Rees, *Colloid Interface Sci.*, 1972, **40**, 206)

data for restricted diffusion is shown in Figure 8. The echo attenuation is displayed as a function of the diffusion time Δ , for different gradient strengths. It can be seen that the characteristic of restricted diffusion is that the echo attenuation reaches a limiting value (when $\Delta \gg L^2/D$), and that this limit and the echo attenuation in general are functions of q and Δ as independent variables.

As pointed out above (Section 2.3), in cases other than that of plane parallel barriers, calculation of the echo response for restricted diffusion has required the assumption of a Gaussian distribution of phases at all times.^{14,15} As mentioned in

Section 2.3, this assumption, and the accuracy of the short gradient pulse limit has been studied by Balinov et al.³¹ using computer simulations.

PGSE experiments in situations where diffusion is restricted may be used to characterize the distributions of sizes of such barriers to diffusion, usually with some assumed form of the distribution.^{32,33} A complication which has only recently begun to be addressed is that, in many systems containing barriers to diffusion on the micrometer scale, the spin relaxation behavior may also be dominated by diffusion to the surface of the barriers.^{34,35} In order to determine accurately information concerning the compartment sizes bounding the diffusion, the PGSE experiment must be analyzed taking these surface relaxation effects into account.

3.2 Hindered and Anisotropic Diffusion

As indicated above, hindered diffusion is taken as describing any situation in which the propagator $P(\mathbf{r}, \Delta; \mathbf{r}_0)$ evolves in a non-Gaussian fashion and the mean-squared displacements are not bounded. Examples of this could be permeable barriers such as membranes or polymers,^{23,36} intra- and inter-crystallite diffusion in zeolites and related materials,²³ polymer solutions and melts,^{36,37} fluids contained in porous solids,^{7-9,24} and colloidal and multiphase systems.¹¹ A number of approaches have been developed to allow the interpretation of PGSE data arising from such situations.^{6-9,24-26,28,35,37} It is not the purpose of this article to provide a detailed account of all these aspects, and many of the ideas and principles involved have been introduced earlier. However, as an illustration, the case of diffusion through a porous solid will be described. Typically, this might concern the diffusion of molecules through an array of pores, these having a characteristic dimension a , which are connected in some manner in three dimensions with a separation b . Under the so-called 'pore equilibration assumption',⁸ which requires that once a molecule transfers to a neighboring pore its spatial distribution is immediately taken to be the pore volume, the PGSE response has the form

$$S(q, \Delta) = |I(q)|^2 F(q, \Delta) \quad (40)$$

where $I(q)$, the structure factor of a single pore, is given by equation (37) and $F(q, \Delta)$ describes the details of the motions between pores. For an array of pores which have the nature of a single crystal and using a pore hopping formalism to describe the diffusion between pores, it was found that

$$F(q, \Delta) = \exp[-(4D_{\text{eff}}\Delta/b^2) \sin^2(\pi qb)] \quad (41)$$

whereas for a pore glass configuration in which the pore hops produce a distribution of displacements in the gradient direction,

$$F_G(q, \Delta) = \exp\{-(6D_{\text{eff}}\Delta/b^2)[1 - \sin(2\pi qb)/2\pi qb]\} \quad (42)$$

Equation (41) shows that when $qb = \text{Integer}$, $F(q, \Delta) = 1$ and all dependence of $S(q, \Delta)$ on Δ disappears, whereas for the pore glass there is no such unique condition. Comparison of these analytic results with random walk computer simulations showed that agreement was exact for

$qb = \text{integer}$, with deviations at intermediate qb values which were more significant for more open structures, i.e. when the connections between pores become of increasing importance in terms of fluid content and close in dimensions to the pores themselves. Mitra et al.⁹ derived an alternative description of the behavior for such systems which was exact for the short Δ regime [cf. equation (32)] and, via an ansatz, derived a model for propagator behavior on all Δ and q scales which they suggest is better able to describe diffusion in more open structures. In another approach, describing the combined effects of both diffusion and relaxation in structured systems, typical of cellular biological materials, Hills and Snaar³⁵ showed the necessity of characterizing $S(q, \Delta, \tau)$ (τ being a timescale over which relaxation is occurring in the experiment) over as wide a range of the three variables as possible in order to interpret the data in terms of the structure and dynamics of the systems.

The case of anisotropic diffusion is summarized in the review by Callaghan⁶ as are other forms of nonisotropic diffusion such as curvilinear behavior which might be found in the diffusion of polymer molecules over timescales spanning the tube renewal time.³⁷ The key to distinguishing these situations from restricted/hindered diffusion, is that although $S(q, \Delta)$ is not a simple exponential decay [such as equation (16)] and, typically, may show curved semilogarithmic behavior, it is a function of only the single combined variable $q^2\Delta$.

4 PGSE CHARACTERIZATION OF FLOWING FLUIDS

As pointed out by Callaghan in 1984,⁶ at that time studies of flow using the PGSE approach had not attracted the same level of attention as diffusion. The rapid development of MRI has since changed that situation because of the clinical importance of the flow of fluids throughout the body. As MRI investigations of flow are covered elsewhere in this Encyclopedia, the aim of this section is to provide a basis for understanding the way in which flow processes affect PGSE-type experiments.

The possibility of NMR characterization of flow using spin echoes in the presence of gradients was first proposed by Hahn.³⁸ The area has been reviewed regularly and the reader is referred to the recent account by Caprihan and Fukushima³⁹ for a survey of such reviews and a comprehensive discussion of all aspects of flow measurement using NMR methods. In particular, time-of-flight and MRI approaches may be accessed through this review.

Characterization of the flow of fluids by NMR can probe a wide range of behaviors, including the magnitudes and distributions of flow velocities (which can range from micrometers to meters per second), the detailed nature of the displacements of fluid produced by the flow, whether this be laminar, time varying streamline or turbulent, and the time and spatial scale dependence of these qualities. The general principles governing the PGSE response to flow are those described in Section 2. As pointed out there, the differences between diffusion and flow are to be found in the nature of the propagator $P(x, \Delta; x_0)$, with flow, being to a degree a directed and coherent process, producing asymmetric development of the propagator with respect to $(x - x_0)$.

4.1 Measurement of Time-Independent Velocities

As discussed in Section 2 [equation (4) and (6)] for a system in which all spins move with the same and time-independent velocity in the gradient direction during the time Δ , referred to as ‘plug flow’, the PGSE response has the form:

$$S(q, \Delta) = S(0) \exp(iq\Delta v) \quad (43)$$

Thus, the echo amplitude, detected with a phase sensitive detector, will exhibit a sinusoidal variation with $q\Delta$. Note that the magnitude of the signal is unaffected by plug flow and, under these conditions, would be damped only by spin relaxation processes.

In the case of laminar flow of a fluid there always exists a distribution of velocities $P(v)$, the form of which is characteristic of the geometry of the flow channel. The echo response of the PGSE experiment under these circumstances is:

$$S(q, \Delta) = S(0) \int P(v) \exp(iq\Delta v) dv \quad (44)$$

i.e. the Fourier transform of $P(v)$. Thus, for example, for laminar flow in a circular pipe with the gradient oriented along the pipe axis

$$S(q, \Delta) = S(0) \text{sinc}(4\pi q\Delta\langle v \rangle) \quad (45)$$

This can be deduced quite simply from equation (44) by noting that, for this flow situation, $P(v)$ is rectangular, having uniform intensity ($\frac{1}{2}\langle v \rangle$) up to $v = v_{\max} = 2\langle v \rangle$, where $\langle v \rangle$ is the average velocity.⁴⁰ The Fourier transform of such a rectangular function is the sinc function.²⁷ equation (45) shows that, in general, the presence of a velocity distribution, produces a damping of the PGSE signal, proportional to the inverse of the width of $P(v)$, and a net phase shift.

4.2 Effects of Time-Dependent Velocities

In many systems of interest, medical, biological or physicochemical, fluid flow occurs such that the velocity of any fluid element projected onto the gradient direction will exhibit some time dependence. For example, fluid moving through a channel which varies in dimensions will have a time varying velocity. Similarly, if the flow channel direction changes, the projection of the fluid velocity onto the gradient will be time dependent. For slow flows, diffusion can cause spins to sample a range of velocities within $P(v)$, whilst turbulence also introduces time dependence. In a qualitative sense, such time dependence of velocity could be thought of in terms of a diffusion-like process and indeed the term ‘pseudodiffusion’ has been used in this context.^{41–43} As such, it might be expected that this would introduce a further damping of the echo signal. However, relative to the effects of a given time-independent $P(v)$, time-dependent sampling by spins of this $P(v)$ during Δ will have an effect similar to motional narrowing of spectral lines and will cause a reduction in the loss of phase memory which, in the limit, will average to a narrowed effective $P(v)$ corresponding to a single average velocity.

In the MRI literature an approach to time varying velocities has been developed⁴³ which starts from the requirement to calculate the phase shift from the expression

$$\phi = \int x(t)g(t) dt \quad (46)$$

which allows for finite gradient durations. The position $x(t)$ is expanded as a power series

$$x(t) = x_0 + vt + \frac{1}{2}at^2 + \frac{1}{6}jt^3 + \dots \quad (47)$$

where v , a , and j are the first, second and third time derivatives of $x(t)$ corresponding to velocity, acceleration, and ‘jerk’, respectively. This analysis leads to the design of gradient pulse profiles which can be used either to null specific orders in this series or to sensitize experiments to these orders.⁴³

For the case in which fluid moves through small vessels with a mean velocity $\langle v \rangle$, and where these paths change direction at random with a characteristic length l , the pseudodiffusion coefficient is given by:^{41–43}

$$D_p = \langle v \rangle l / 6 \quad (48)$$

Further discussion of these and related situations, including turbulent flow, are given by Caprihan and Fukushima.³⁹

4.3 Multiple Pulse and Other Sequences for Characterizing Flow

The simple PGSE and related PGSTE sequences have the disadvantage, for both diffusion and flow, that they must be repeated for appropriate ranges of the variables q and Δ . As such, they are time consuming and, for the case of flowing systems, this can lead to problems with non-steady-state phenomena. Use of sequences which capture the effects of flow in as short a time as possible are therefore desirable. Carr and Purcell² showed that in the $90^\circ - \tau - (-180^\circ - 2\tau -)_n$ - multiple echo sequence, only odd numbered echoes were affected by flow (convection), the even echoes decaying solely through T_2 effects and diffusion. This realization led to the development of new multiple pulse sequences which, in the presence of applied gradients, allowed a cumulative effect of flow on echo amplitudes to be achieved.^{44,45} More recently, use of the Carr–Purcell type sequence together with the Karlicek and Lowe alternating gradient concept has been used to allow the effects of flow to be maximized, whilst discriminating against the effects of diffusion through internal gradients.⁴⁶

Other approaches to enhancing the capability to measure flow, particularly for low velocities, include the direct measurement of time shifts of the echoes measured with a frequency offset, which has been used to measure directly the drift motion of ions in solution driven by an electric field,^{47,48} and the development of two-dimensional methods.^{48,49}

These latter developments are of considerable interest and, whilst details are available elsewhere in this Encyclopedia and in the references cited in this article, some general points are worth highlighting in this introductory account. In the development of what is termed ‘electrophoretic NMR’, Johnson and He⁴⁸ have pointed to the close analogy in formalism between the optical method of holographic

relaxation spectroscopy (HRS) and the PGSTE experiment in which the echo signal is measured in the presence of a gradient.⁵⁰ This can be appreciated by considering the nature of $M_z(x)$, the magnetization existing during the time T in the PGSTE sequence (Figure 4) and from which the STE derives. $M_z(x)$ has the form

$$M_z(x) = 0.5M_0 \cos(2\pi qx) \quad (49)$$

which is analogous to the transient grating produced optically in HRS. In both cases, diffusion or flow either damp or shift the gratings, and these effects may be imaged through application of a 'read' gradient in the place of the second gradient pulse or, for HRS, by laser diffraction. The concept of imaging the spatial magnetization distribution in PFG-type experiments (as distinct from MRI) is of interest both for the insight it generates, through analogies with optical phenomena, and for the additional information it makes available. This is shown clearly by the use of this approach by Frydman et al.⁴⁹ for the characterization of flow.

The sequence used by Frydman et al. is essentially that shown in Figure 1, except that the echo is captured in the presence of a gradient. Their actual experiment is shown in Figure 9(a), whilst Figure 9(b) illustrates the characteristic two-dimensional plots obtained which correlate the separately-determined x_0 and $X(\Delta)$ for the case of Taylor vortices in Taylor–Couette flow. As pointed out,⁴⁹ this approach has the merits of providing a global view of the particle displacements, yielding a Lagrangian, as compared to an Eulerian, view of the flow behavior.

Figure 9 (a) The pulse sequence used to determine the correlation between the starting position x_0 and diffusional displacement $X(\Delta)$ [$=x(\Delta) - x_0$]. A slice selection is used to define a plane of spins and this is followed by a PGSE experiment in which the echo is recorded in the presence of the second gradient pulse. 1 INTRODUCTION

Porous media are of considerable interest in a very diverse range of activities. Porous media comprise a wide variety of substances—plastics, ceramics, cements, clays, rocks, porous glasses, carbons, silica gels, and zeolites. Even biological tissues may share many features of porous media. Depending on the given nature, the pore diameters in these substances may range from the subnanometer region up to macroscopic dimensions. The efficiency of their technical use is intimately connected with their transport properties. Diffusion measurements in porous systems are therefore of direct practical relevance. Moreover, systematic diffusion studies in such systems may contribute to a better understanding of such fundamental questions as the interaction between molecules and solid surfaces,^{1–3} and the behavior of molecular systems of reduced dimensionality.⁴

Among the methods of studying molecular diffusion in porous media, NMR spectroscopy is of particular relevance. As a noninvasive method, it allows the observation of molecular transportation without interfering with the internal processes. The technique may be applied under both equilibrium and nonequilibrium conditions. Using different NMR techniques, various aspects of molecular transport may be investigated, including the elementary processes of diffusion and the rate of molecular propagation over microscopic and macroscopic distances. A review of the principles of these techniques and examples of their application is given in Section 2. Probably the most powerful NMR method for studying molecular propagation is the pulsed field gradient method (PFG-NMR), and this is described in more detail in Section 3. The capability of PFG-NMR to trace indications of anomalous diffusion in porous media is discussed in Section 4. Finally, as an illustration of the versatility of PFG-NMR, Section 5 summarizes the information provided by this method about molecular diffusion in beds of microporous crystallites (zeolites).

2 PIECES OF INFORMATION

The most straightforward way of applying NMR to study diffusion in porous media is based on the fact that the intensity of an NMR signal is directly related to the

number of the observed nuclei. Using this correlation it was possible to measure the rate of molecular exchange between zeolite crystallites of type ZSM-5⁵ and NaX,⁶ loaded with ordinary (i.e. hydrogen containing) benzene and the surrounding atmosphere of deuterated benzene. The intracrystalline diffusivities estimated on the basis of the measured exchange rates were in excellent agreement with the data determined directly by PFG-NMR in the identical sample and verified the equivalency of macroscopically and microscopically measured diffusivities.

The information provided by the NMR signal intensity is significantly enhanced when the measurements are performed under the influence of well defined inhomogeneities of the magnetic field. Under such conditions, the resonance frequency becomes space dependent, so that the NMR spectrum may be directly correlated with the distribution of the nuclei under consideration within the sample. This method has become popular under the names 'NMR tomography' or 'NMR spin mapping', due to its spectacular progress in application to anatomical imaging in medicine⁷ (cf. articles on biomedical applications in this Encyclopedia). However, its application is certainly not confined to biomedicine; in particular, a wide variety of NMR imaging studies have been concerned with molecular propagation in porous media.^{8,9} A summary of the most recent results may be found in the proceedings of the 'International Meeting on Recent Advances in NMR Applications to Porous Media', Bologna, 1990,¹⁰ and Canterbury, 1993.¹¹

An interesting possibility of tracing mass transfer in porous systems is provided by ¹²⁹Xe NMR.¹² For this purpose, the system under study is brought into contact with a xenon atmosphere. Since, besides the pore architecture and the chemical composition of the pore surface, the chemical shift of ¹²⁹Xe NMR also depends on the nature and the concentration of the molecules in the interior of the porous system, the ¹²⁹Xe NMR spectrum reflects the distribution function of molecular concentrations within the sample. If there are, for example, two regions of different concentration of the molecular species under study, the ¹²⁹Xe NMR spectrum should consist of two different lines. Obviously, the merging rate of the two lines is directly correlated with the rate of equilibration of the internal concentration, and provides direct information about the intrinsic diffusivities. This measuring principle has been used to study molecular transportation in both the micropores¹³ and the macropores^{14,15} in zeolitic adsorbate–adsorbent systems.

In the methods so far mentioned, we have exclusively considered samples that are not at equilibrium, either in the strict macroscopic sense, or at least with respect to the different isotopes involved. As soon as equilibrium is attained, these methods cannot provide any information about molecular diffusion. It is one of the great advantages of NMR spectroscopy to be able to follow even the molecules themselves on their individual diffusion paths. The information thus obtained may concern the elementary steps of diffusion as well as the rate of molecular propagation over much larger distances. Information about the elementary steps of diffusion of molecules under the influence of the internal system of porous media may be deduced from an analysis of the nuclear magnetic relaxation times and the NMR spectra.

Proton magnetic relaxation studies offer the advantage that most molecules of interest in diffusion studies of porous media

contain hydrogen atoms, and that, except for the non-naturally-occurring tritium, the magnetogyric ratio, and hence the signal-to-noise ratio, is largest for the hydrogen nucleus.¹⁶ Proton magnetic relaxation of molecules in contact with solid surfaces is mainly determined by magnetic dipole interaction with protons of the same molecule (intramolecular proton–proton interaction), with protons of other molecules (intermolecular proton–proton interaction), and with paramagnetic ions. The different contributions may be separated by a ‘relaxation analysis’.¹⁷ Except for extremely pure substances, longitudinal relaxation is controlled by the magnetic dipole interaction with paramagnetic ions. If the longitudinal electron spin relaxation time of these paramagnetic ions is much greater than the mean residence time between subsequent diffusion jumps, then proton magnetic relaxation is affected by the translational motion of the molecules with respect to the ions, and the temperature dependence of the longitudinal relaxation time is found to pass a distinct minimum, which is characterized by the condition that at this temperature the mean residence time is of the order of the reciprocal of the resonance frequency.¹⁷

The problem of separating the various contributions to nuclear magnetic relaxation can be overcome to a certain degree by studying the deuteron magnetic resonance. This is due to the almost completely dominant interaction energy of the electric quadrupolar moment of the deuteron with the intramolecular electric field gradient at the nuclear site in comparison with the various magnetic coupling energies. Since the deuteron magnetic resonance frequency depends on the orientation of this electric field gradient with respect to the external magnetic field, molecular reorientations with time constants of the order of the reciprocal of the linewidths will lead to characteristic changes in the NMR spectra, including a narrowing of the total spectrum.^{18,19} The thus-estimated reorientation times for several hydrocarbons in X-type zeolites were found to be in excellent agreement with the directly measured diffusivity, if one assumes that the molecular mean jump lengths are of the order of the distance between neighboring supercages.²⁰

In an identical manner, molecular reorientation also leads to a narrowing of NMR lines in the case of chemical shift anisotropy. Measurements of this type have been carried out with various nuclei (¹³C and ³¹P), and numerical simulations have been developed to allow the measured spectra to be attributed to the corresponding reorientation times in the relevant geometry.^{21,22}

Since the confinement of the molecules to the internal surface of porous media often leads to a preferential orientation of the molecules, the orientation correlation function will generally not decay to zero by mere local reorientation. Rather, the complete decay to zero necessitates molecular migration to positions with changed orientational preference. This process of ‘reorientation mediated by translational displacements’ (RMTD)²³ may be traced by measuring the longitudinal nuclear magnetic relaxation times in the range of low resonance frequencies (in particular by the field cycling technique²⁴), corresponding to the large correlation times of this process. Tracing RMTD has been shown to be an informative tool for studying both molecular dynamics and structural properties in micrometer and submicrometer length scales of porous systems.^{23,25}

In more open porous structures, overall nuclear magnetic relaxation is significantly influenced by the rate of exchange

between the region of intense relaxation (the magnetization ‘sinks’) and the bulk phase. The theoretical analysis of this situation^{26,27} shows that the relaxation pattern is controlled by the relationship between the mean diffusion time over a characteristic length scale of the individual pores (e.g. their radius) and the overall relaxation time to be expected under the condition of fast exchange. For diffusion times exceeding the (hypothetical) overall relaxation time, the observed relaxation behavior depends notably on the exchange conditions, yielding information about both the pore sizes and the intrinsic diffusivities.^{26–28}

At the beginning of this section ¹²⁹Xe NMR was introduced as a tool for following the evolution of molecular concentration profiles within porous media. This technique clearly includes the observation of the distribution of the xenon atoms themselves. In microporous materials where the individual cavities are separated by narrow ‘windows’, the population distribution of the xenon atoms within the individual cavities may be determined.²⁹ In addition to this local structural information, by using a second time dimension in the NMR experiments (two-dimensional exchange NMR), one may even determine the rate of molecular exchange between cavities of different occupation numbers. This method has been successfully applied to the study of intracrystalline diffusion of xenon in NaA-type zeolites.³⁰

Common to all the methods so far considered is the fact that the information about molecular self-diffusion is based on the applicability of certain models. There is, however, the possibility of monitoring directly the probability distribution of molecular propagation. This possibility is provided by transient NMR measurements in a magnetic field with well-defined inhomogeneities of large intensity. The most important representative of these techniques, PFG-NMR, is described in more detail in the rest of this article.

3 PRINCIPLES OF PFG-NMR

The principles of diffusion measurement by NMR may be easily visualized by using the classical concept of nuclear magnetism. According to this concept, any individual spin will carry out a precessional motion about the direction of the constant magnetic field with a precessional frequency given by the Larmor relationship:

$$\omega = -\gamma B \quad (1)$$

where γ is the magnetogyric ratio. In PFG-NMR, the constant magnetic field is superimposed over two short time intervals δ by an inhomogeneous field

$$B_{\text{add}}(\mathbf{r}) = \mathbf{g} \cdot \mathbf{r} \quad (2)$$

the so-called ‘field gradient pulses’. According to equation (1) these pulses have the effect that the positions of the individual spins at the instants of the field gradient pulses are recorded by the precessional phases

$$\phi(\mathbf{r}) = \int \omega dt = -\gamma(B + \mathbf{g} \cdot \mathbf{r})\delta \quad (3)$$

accumulated during these time intervals. The two field gradient pulses are generally incorporated into the classical $\pi/2-\tau-\pi$ rf pulse sequence which gives rise to a transient NMR signal (the ‘spin echo’) at time 2τ after the initial $\pi/2$ pulse. Being proportional to the total magnetization, the intensity of the spin echo depends on the dephasing of the precessional phases of the individual spins at time 2τ . Since the dephasing effected by the first field gradient pulse according to equation (3) is inverted by the π pulse, for immobile spins it is exactly compensated by the second field gradient pulse which is applied after the π pulse. However, if the individual molecules (and with them the spins) have moved during the time interval between the field gradient pulses, the refocusing will be incomplete and the intensity of the transverse magnetization will not be fully restored to its original value. NMR signal attenuation must therefore be expected to increase with increasing displacements during the ‘observation time’ (i.e. the time interval between the two field gradient pulses), and with increasing width δ and amplitude g of the field gradient pulses.

For a quantitative analysis we consider a particular spin which has been at positions $\mathbf{r}_1$ and $\mathbf{r}_2$ during the first and second field gradient pulses, respectively. According to equation (3), the phase shift of such a spin in comparison with a spin fixed in space is equal to $\gamma\delta\mathbf{g}\cdot(\mathbf{r}_2 - \mathbf{r}_1)$. The total magnetization is the vector sum of the dipolar moments of the individual spins. Thus, in complex notation, the vector sum of the transverse nuclear magnetic moments of all spins involved yields

$$\Psi = \int \int \exp[i\gamma\delta\mathbf{g}\cdot(\mathbf{r}_2 - \mathbf{r}_1)] p(\mathbf{r}_1) P(\mathbf{r}_2, \mathbf{r}_1, \Delta) d\mathbf{r}_1 d\mathbf{r}_2 \quad (4)$$

where Ψ denotes the ratio between the NMR signal intensity observed with and without magnetic field gradient pulses, $p(\mathbf{r}_1)$ denotes the probability (density) of finding a spin at position $\mathbf{r}_1$ (i.e. during the first magnetic field gradient pulse), and $P(\mathbf{r}_2, \mathbf{r}_1, \Delta)$ denotes the probability (density) that a spin which has been at position $\mathbf{r}_1$ during the first field gradient pulse will have come to $\mathbf{r}_2$ after a time interval Δ (i.e. during the second field gradient pulse). As it contains the complete information about the process of molecular propagation, the function $P(\mathbf{r}_2, \mathbf{r}_1, \Delta)$ has been termed the ‘propagator’. (This expression must clearly not be confused with the operator $\hat{U}(t)$ which is generally termed in the same way and describes the evolution of the ensemble of the magnetically resonant nuclei under study.) Integrating over all possible starting positions $\mathbf{r}_1$, one may introduce a mean propagator³¹

$$P(\mathbf{r}, \Delta) = \int p(\mathbf{r}_1) P(\mathbf{r}_1 + \mathbf{r}, \mathbf{r}_1, \Delta) d\mathbf{r}_1 \quad (5)$$

which denotes the probability that during time Δ an arbitrarily selected molecule within the sample will be displaced over $\mathbf{r}$. With this notation, equation (4) becomes

$$\Psi = \int \exp[i\gamma\delta\mathbf{g}\cdot\mathbf{r}] P(\mathbf{r}, \Delta) d\mathbf{r} \quad (6)$$

Since equations (4) and (6) formally coincide with the expressions for the intermediate incoherent scattering function in

neutron scattering, PFG-NMR has been repeatedly interpreted as a scattering experiment^{32–35} with a generalized scattering vector

$$\mathbf{k} = \gamma\delta\mathbf{g} \quad (7)$$

The maximum value of this quantity is of the order of 10^7 m^{-1} , yielding a lower limit of about 100 nm for the space scale covered in PFG-NMR experiments. The much larger scattering vectors in neutron scattering experiments confine diffusion measurements by this technique to maximum displacements of the order of only a few nanometers. Hence, for the observation of molecular transportation phenomena on the micrometer scale, PFG-NMR represents a unique method.

PFG-NMR has been successfully applied to the study of molecular diffusion in a wide spectrum of substances, including pure liquids and gases, polymers, liquid crystals, membranes, biological tissues, as well as the vast group of porous media. Detailed introductions to the experimental procedure with special emphasis on the various techniques which may be applied to enhance the sensitivity of this method and to circumvent the omnipresent pitfalls in experimental work may be found in the literature.^{33–39} In most cases, molecular diffusion, as observed by PFG-NMR, is considered to follow the laws of ordinary diffusion. The validity of this assumption is considered in the next section.

4 ORDINARY VS ANOMALOUS DIFFUSION

The total molecular displacement of any molecule during the observation time Δ of a PFG-NMR experiment may be understood as the result of the displacements of this molecule during the different time intervals into which the observation time Δ may be subdivided. Under the assumption that subsequent displacements are independent of each other and are controlled by the same probability distribution then, according to the central limit theorem of statistics for a sufficiently large number of time intervals, the distribution of the sum of these displacements will be given by a Gaussian function with a mean square distribution being proportional to the number of time intervals considered and, hence, to the observation time. Since this probability distribution is in fact the propagator, in the case of three-dimensional diffusion, for example, we may thus write

$$P(\mathbf{r}, \Delta) = (4\pi D\Delta)^{-3/2} \exp(-r^2/4D\Delta) \quad (8)$$

where the self-diffusion coefficient D has been introduced via the required proportionality between the mean square displacement and the observation time:

$$\langle r^2(\Delta) \rangle = 6D\Delta \quad (9)$$

Molecular random walk following equation (8) [and hence equation (9)] is called ‘ordinary diffusion’. It is completely described by the self-diffusion coefficient D . The definition of the self-diffusion coefficient by the Einstein relationship [equation (9)] is equivalent to that by Fick’s first law:⁴⁰

$$\mathbf{j}^* = -D \nabla c^* \quad (10)$$

where the self-diffusion coefficient is introduced as the factor of proportionality between the negative concentration gradient and the flux density of labeled molecules at macroscopic equilibrium. Inserting equation (8) into equation (6), one obtains for the signal attenuation in PFG-NMR for ordinary diffusion:

$$\Psi = \exp(-\gamma^2 \delta^2 g^2 D \Delta) \quad (11)$$

With equation (9), signal attenuation may also be expressed as a function of the mean square displacement:

$$\Psi = \exp(-\gamma^2 \delta^2 g^2 \langle r^2 \rangle / 6) \quad (12)$$

In deriving equation (4) [and hence equations (11) and (12)] it has implicitly been assumed that the molecular displacements during the field gradient pulses are much smaller than those in the interval between the two gradient pulses (narrow-pulse limit).³³ Only under this assumption can the NMR signal attenuation be related to the propagator in such a straightforward way. In the case of ordinary diffusion, the finite field gradient pulse width may be exactly taken into account by replacing Δ by an ‘effective’ observation time $\Delta - \delta/3$.

Any violation of the conditions for the applicability of the central limit theorem must be expected to lead to deviations from ordinary diffusion. Very often, in particular considering molecular diffusion in fractal networks, in the case of ‘anomalous’ diffusion the mean square displacement should obey a simple scaling law

$$\langle r^2(t) \rangle \propto t^\kappa \quad (13)$$

where now, in contrast to ordinary diffusion, the time exponent κ is smaller than 1. It may be shown⁴⁰ that the fractal dimension of the trajectory of a random walker obeying equation (13) is equal to $2/\kappa$. As a simple inversion of the central limit theorem, one may conclude that in the case of anomalous diffusion subsequent displacements must be correlated. Analytical expressions for this correlation may be deduced from equation (13).⁴¹ By using these expressions it can be shown that in the narrow-pulse approximation for anomalous diffusion the PFG-NMR spin echo attenuation is also given by equation (12). For finite pulse widths δ , the expression for the spin echo attenuation is more complicated⁴¹ and cannot be deduced from the narrow-pulse approximation by simply introducing an effective observation time.

The search for indications of anomalous diffusion is a current topic of PFG-NMR. Recent progress in the sensitivity towards smaller molecular displacements, in particular including the possibilities of the stray-field modification of the steady-gradient spin echo NMR method,⁴² did in fact allow the observation of anomalous diffusion in polymer melts and solutions.^{34,43,44} Scaling laws with time exponents κ differing in the range 0.25–0.5 could be confirmed, partially by varying the observation time over orders of magnitude. No similar breakthrough in detecting indications of anomalous diffusion in porous media has yet been achieved. As an example, Figure 1 shows the mean square displacement of *n*-hexadecane adsorbed on active carbon as a function of the observation time.⁴⁵ Over two orders of magnitude the observed time dependence is in complete agreement with that of ordinary diffusion,

Figure 1 Mean square displacement of *n*-hexadecane adsorbed on active carbon at a pore filling factor of 0.43 versus observation time Δ at: (○) 291 K, (□) 323 K, (△) 363 K, and (◇) 413 K. The straight line indicates the dependence⁴⁵ $\langle r^2(\Delta) \rangle \propto \Delta$

although the internal pore system can be described by introducing fractal dimensions. One should note, however, that in the measurements there was only a very small overlap between the pore distribution function and the minimum displacements observable by PFG-NMR.

Molecular transportation in porous crystallites over distances sufficiently exceeding the dimensions of the elementary units clearly fulfils the conditions for the application of the central limit theorem. It is not surprising, therefore, that PFG-NMR measurement of intracrystalline diffusion in zeolites has not thus shown any deviation from ordinary diffusion. There is, however, an intriguing exceptional case, where even in zeolites molecular transportation must be expected to deviate from ordinary diffusion. Such a situation may occur when the zeolite pore system consists of parallel channels, as for example in zeolites ZSM-12 or $\text{AlPO}_4\text{-5}$. As soon as the channel diameters are so small that the molecules cannot pass each other, by theoretical considerations⁴⁶ the molecular mean square displacement may be shown to be proportional to the square root of the observation time rather than to the observation time itself. The experimental verification of this phenomenon of ‘single-file’ diffusion⁴⁷ is a task for PFG-NMR.

In the following final section, by reviewing selected PFG-NMR studies on zeolites, typical examples are given of the application of this NMR technique to diffusion measurements in porous systems. The variety of attainable information will demonstrate that the confinement to ordinary diffusion in these

substances in no way diminishes the attractiveness of such investigations.

5 DIFFUSION IN MICROPOROUS CRYSTALLITES (ZEOLITES)

According to the original definition, zeolites are microporous crystalline aluminosilicates. In the last few years, dramatic progress in zeolite synthesis has made possible the production of a large number of zeolite structure types with the aluminum and/or silicon atoms replaced by other components such as phosphorus, gallium, germanium, boron, and beryllium. Moreover, with these new structural components, a number of new structure types have been realized which have no equivalent among the aluminosilicates.⁴⁸ It has become common use, therefore, to apply the term 'zeolites' quite generally to microporous crystalline solids. The diameters of the zeolite crystallites are typically in the micrometer range. Therefore, molecular propagation within beds of zeolite crystallites proceeds both within the individual crystallites (in the 'micropores') and in the intercrystalline space (the macropores or

transport pores). In the case of gas phase adsorption, which we shall consider exclusively in the following discussion, molecular concentration in the intercrystalline space is negligibly small in comparison with intracrystalline concentration.

A survey of the different features of molecular transportation as accessible by PFG-NMR under such conditions is provided by the propagator representation. As an example, Figure 2 shows the mean propagator of ethane in zeolite NaCaA³¹ for two different crystallite sizes at three different temperatures, determined from the measured spin echo attenuations by using the inversion of equation (6). Depending on the crystallite size, the observation time and the temperature, the observed mean propagator may be exclusively determined by intracrystalline diffusion [e.g. in Figure 2(a) at 153 K] or by migration through the bed of crystallites ['long-range' diffusion, in Figure 2(b) at 293 K]. In the intermediate range between these two limiting cases, the propagator additionally depends on the rate of molecular exchange between the intra- and intercrystalline spaces. Under appropriate conditions, PFG-NMR is therefore able to provide three different dynamic quantities: the coefficients of intracrystalline and of long-range self-diffusion, and the intracrystalline mean lifetime.

Figure 2 Propagator representation for the self-diffusion of ethane in NaCaA zeolites: (a) 40 mg g⁻¹, $R \approx 8 \mu\text{m}$; (b) 58 mg g⁻¹, $R \approx 0.4 \mu\text{m}$ ³¹

A detailed description of the procedure and examples of application may be found in the literature.^{40,49}

At sufficiently low temperatures, the thermal energy of the adsorbate molecules is not high enough to allow them to overcome the step in the potential energy from the intracrystalline to the intercrystalline space. The molecules are confined, therefore, to the interior of the individual crystallites, and the situation is comparable to that within a pore with impenetrable walls,⁵⁰ where now the pore size corresponds to the size of the crystallites. Following the scattering analogy, the PFG-NMR spin echo attenuation due to diffusion between connected pores has been used to analyze the pore distribution and connectivity.^{51,52} It is a challenge for PFG-NMR to adopt this concept to study molecular exchange between the different crystallites in the transition range between 'restricted' and long-range diffusion.

One of the most remarkable features of intracrystalline diffusion is the large variety of patterns of concentration dependence. So far, at least five different types of concentration dependence have been observed. Examples of adsorbate-adsorbent systems that follow these different patterns are presented in Figure 3.⁴⁰ It is an attractive task for molecular dynamics simulations to correlate the different patterns with possible microdynamic models.⁵³⁻⁵⁵

A large number of zeolite structure types are of noncubic symmetry, so that intracrystalline molecular migration must be described by a diffusion tensor rather than by a diffusion coefficient, i.e. a scalar quantity. As a consequence of the

Figure 3 Patterns of the concentration dependence of intracrystalline diffusivities. I, *n*-Hexane in NaX at 358 K. II, (Δ) *ortho*-, ($\square$) *meta*-, and ($\blacktriangle$) *para*-xylenes in NaX at 393 K. III, Ammonia ($\circ$) and water ($\bullet$) in NaX at 298 K. IV, Acetonitrile in NaX at 393 K. V, ($\circ$) Ethane at 173 K and (Δ) propane at 413 K in NaCaA⁴⁰

microscopic size of the crystallites, only recently have PFG-NMR measurements of diffusion anisotropy in zeolites become possible. The measurements have been carried out in two different ways: (i) by introducing the zeolite crystallites into an array of parallel capillaries with their longitudinal extension preferentially parallel to the capillary axes; and (ii) by analyzing the shape of the signal decay function.^{56,57} In both cases, the measured diffusivities (methane and ethane in zeolite ZSM-5) were found to be in satisfactory agreement with the results of molecular dynamics simulations.^{53,54}

As a noninvasive method, PFG-NMR represents an excellent tool for the in situ observation of molecular transportation under reaction conditions. As an example, Figure 4 represents the results of Fourier transform PFG-NMR measurements^{56,58} of the time dependence of the diffusivities of the reactant and the product molecules during the conversion of cyclopropane to propene on zeolite NaX.⁵⁹ In addition, Figure 4 also shows the relative amount of both species as determined by analyzing the free induction decay. Comparing the intrinsic reactivities with the rather high intracrystalline mobilities, any essential influence of molecular transport on the rates of molecular conversion in flow reactors may be excluded. Using zeolite crystallites of different size, this prediction could in fact be confirmed by direct measurement in flow reactors.⁵⁹

Since the first applications of PFG-NMR to study intracrystalline diffusion in zeolites, repeatedly dramatic differences between these data and the results of conventional sorption measurements have been stated.^{17,40} This discrepancy led to a critical reexamination of the earlier sorption data, which revealed that in many cases the effects of external heat- and mass-transfer resistances in limiting the adsorption-desorption rates were far greater than originally assumed, and the discrepancy with the NMR data could be explained on this

Figure 4 Time dependence of the relative amounts of cyclopropane and propene during the conversion of cyclopropane to propene in NaX and their self-diffusion coefficients at 473 K⁵⁹

basis. Moreover, as the PFG-NMR data are in satisfactory agreement with the results of quasielastic neutron scattering experiments⁶⁰ and with molecular dynamics simulations,^{53,54} there should be no doubt that PFG-NMR yields the correct values for the intracrystalline mobility under equilibrium conditions.

A comparison with the results of adsorption-desorption measurements is complicated by the fact that the latter experiments are carried out under nonequilibrium conditions, yielding transport- rather than self-diffusivities.⁴⁰ However, being based on the same elementary processes, i.e. the stochastic movement of the individual molecules, at least for small concentrations, agreement between the transport- and self-diffusivities should be expected. For A-type zeolites this agreement has in fact repeatedly been confirmed.^{40,61,62} Remaining differences, mainly observed for zeolites NaX and ZSM-5, are difficult to explain. Following the adsorption process of *n*-hexane in beds of zeolites NaX by space- and time-resolved PFG-NMR, the molecular mobility of the *n*-hexane molecules immediately after adsorption was found to coincide with that at equilibrium.⁶³ Therefore, as a possible explanation of this discrepancy, it must also be excluded that the diffusivities as obtained by PFG-NMR with sealed samples are only attained after some period of relaxation within the adsorbate-adsorbent system. It is one of the current tasks of zeolite research to decide whether the remaining differences are real indications of different transport properties under equilibrium and nonequilibrium conditions, or whether they are mere consequences of not yet revealed shortcomings in the experimental procedure.

Acknowledgments

The development of PFG-NMR for the study of molecular diffusion in porous media, particularly in zeolites, has profited significantly from the continuous engagement of Harry Pfeifer, one of the pioneers of NMR in Central Europe (see *Pfeifer, Harry: Leipzig, Summer 1951*). I have had the privilege of personal contact and many stimulating discussions with him over many years, and I would like to thank him for his continuous help and encouragement and for countless discussions

1 INTRODUCTION

NMR measurements of diffusion in rare gas solids offer the opportunity for comparisons^{1,2} with the predictions of theory, with tracer results, and with beautiful non-NMR data on energies of vacancy formation. The employment of NMR studies of ultraslow motion³⁻⁴ has produced diffusion data over ranges of nine orders of magnitude.

Pure neon, argon, krypton, and xenon form face-centered cubic (f.c.c.) solids. Self-diffusion proceeds via thermally-activated monovacancy diffusion, with a divacancy population negligible even at the melting point. The temperature variation of the diffusion coefficient follows an Arrhenius relationship with an activation energy which reflects the monovacancy formation and mobility energies:

$$E_D = E_F + E_M \quad (1)$$

NMR measurements on diffusion in solid neon, krypton, and xenon have been reported on the nuclides ²¹Ne, ⁸³Kr, ¹²⁹Xe, and ¹³¹Xe. ¹²⁹Xe has spin $\frac{1}{2}$; ²¹Ne and ¹³¹Xe have spin $\frac{3}{2}$; and ⁸³Kr has spin $\frac{9}{2}$. NMR diffusion results have been inferred from the temperature variations of relaxation times T_1 , T_2 , and $T_{1\rho}$. The present article also touches upon the impurity diffusion of N₂, H₂, and HD in various rare gas solids. Solid helium is not included in the discussion.

Reported measurements⁵⁻⁷ of lengths and lattice parameters have yielded vacancy formation energies E_F . In the case of ⁸³Kr, NMR experiments yield $E_F - E_M$ as well as E_D . For spin- $\frac{1}{2}$ ¹²⁹Xe diffusion parameters are inferred from motional narrowing of the dipolar broadened resonance line. For the quadrupolar nuclides ²¹Ne, ⁸³Kr, and ¹³¹Xe the linewidths include both dipolar and quadrupolar contributions. Intraspin cross relaxation effects⁸ are crucial for understanding the diffusional effects in ⁸³Kr NMR.

2 NEON

Relaxation times T_1 and T_2 have been measured⁹ for ²¹Ne in warm polycrystalline solid neon, isotopically enriched to 51 atom.% ²¹Ne. The open circles in

Figure 1 ²¹Ne spin relaxation times in solid neon. The solid line indicates the temperature dependence anticipated for quadrupolar T_1 . (Reproduced with permission from B. E. Sirovich and R. E. Norberg, *Phys. Rev. B.*, 1977, **15**, 5107)

Figure 1 show T_2 from spin echo envelopes and, below 18 K, from free induction decays. Above 19 K compound envelopes were observed for the spin echoes. The slower component, shown in Figure 1, was interpreted in terms of adiabatic narrowing of the motionally-resolved central ($-\frac{1}{2} \leftrightarrow \frac{1}{2}$) transition.

In the adiabatic limit ($\omega_0\tau_c \gg 1$) it is useful to employ the expression¹⁰

$$\left(\frac{1}{T_2}\right)^2 = \frac{4 \ln 2}{\pi} \sigma^2 \tan^{-1} \left[\frac{\pi \tau_c}{(4 \ln 2) T_2} \right] \quad (2)$$

in which T_2 is the reciprocal of the halfwidth at half-maximum of the motionally-narrowed Lorentzian resonance line. For the well-narrowed line ($\tau_c\sigma \ll 1$), equation (2) reduces to¹¹

$$\frac{1}{T_2} = \sigma^2 \tau_c \quad (3)$$

The data were analyzed in terms of spin-spin relaxation in the case of monovacancy diffusion on an f.c.c. lattice.¹² In the weak-collision limit the result may be written

$$\frac{1}{T_2} = 0.9628 f \alpha \tau \times 2^6 / a_0^6 \quad (4)$$

Here $f = 0.51$ is the ²¹Ne abundance, $\alpha = \frac{3}{2} \gamma^4 \hbar^2 I(I+1)$, and a_0 is the f.c.c. cube edge lattice parameter. Equation (4) corresponds to the expression

$$\frac{1}{T_2} = \frac{4}{3} \sigma_d^2 \tau \quad (5)$$

Here σ_d^2 is the Van Vleck dipolar second moment. Equation (5) states that $1/T_2$ is just $\frac{4}{3}$ times the Anderson-Weiss¹¹ expression for adiabatic narrowing. The τ analysis used the expression

$$\frac{1}{T_2} = 0.85 \times \frac{4}{3} \sigma_d^2 \tau \quad (6)$$

where the factor 0.85 is a compromise between the 'like' coefficient 0.90 and the 'semi-like' coefficient 0.80 for quadrupolar modification of the central line.¹³

The coefficient of atomic self-diffusion based on T_2 for warm solid neon can be computed from τ by using the relationship $D = a_0^2/12\tau$ for diffusion in a f.c.c. lattice of cube edge a_0 . The result is $D = D_0 \exp(-E_D/T)$ with

$$D_0 = 0.15_{-0.07}^{+0.20} \text{ cm}^2 \text{ s}^{-1}, \quad E_D = 475 \pm 19 \text{ K} \quad (7)$$

where the error estimates include both statistical errors and estimated errors on individual data points.

The study of neon diffusion was extended¹⁴ to include ultraslow motions in the cold solid below 15.5 K. The solid circles in Figure 1 indicate $T_{1\rho}$ times measured upon adiabatic demagnetization in the rotating frame (ADRF) to zero B_1 .

In the strong-collision approximation the spin-lattice relaxation rate in the rotating frame may be written¹⁵

$$\frac{1}{T_{1\rho}} = \frac{1}{B_d^2 + B_q^2 + B_{\text{eff}}^2} \left(B_d^2 \frac{1-p_d}{\tau^d} + B_q^2 \frac{1-p_q}{\tau^q} \right) \quad (8)$$

where τ^d and τ^q are, respectively, the characteristic times for significant fluctuations in the dipolar pair energy and the quadrupolar interaction. For uncorrelated self-diffusion $\tau^d = \frac{1}{2}\tau$, where τ is the characteristic time for the atomic diffusion. The dipolar order parameter p_d can be defined as the average dipolar energy per spin after an atomic jump divided by the average dipolar energy before a jump. Similarly, p_q is the ratio of average quadrupolar energies after and before a jump. If the field gradient sources of interest are stationary and the spins move randomly then equation (7) becomes¹⁶

$$\frac{1}{T_{1\rho}} = \frac{1}{B_d^2 + B_q^2 + B_{\text{eff}}^2} \frac{1}{\tau} [2(1-p_d)B_d^2 + (1-p_q)B_q^2] \quad (9)$$

The inclusion of correlations among the motions of spins in the local environment of a particular spin corrects the factor $2(1-p_d)$ to the powder average value 0.882 for vacancy diffusion on a f.c.c. lattice¹⁷ in the case $\tau_v \ll T_2^{\text{RL}} \ll \tau \ll T_1$. Here τ_v is the characteristic time for vacancy motion, and equation (9) becomes

$$T_{1\rho} = \tau \frac{B_d^2 + B_q^2 + B_{\text{eff}}^2}{0.882B_d^2 + (1-p_q)B_q^2} \quad (10)$$

The ^{21}Ne $T_{1\rho}$ data indicated that the static electric field gradients arise from randomly distributed remote defects and that the correlation factor p_q is unity. Equation (10) and the $T_{1\rho}$ data in Figure 1 then produce the self-diffusion results shown in Figure 2 along with those inferred from the T_2 data and equation (6). These data extend over nine orders of magnitude and yield a single Arrhenius result for neon:¹⁴

$$D_0 = 0.15_{-0.02}^{+0.03} \text{ cm}^2 \text{ s}^{-1}; \quad E_D = 475 \pm 3 \text{ K} \quad (11)$$

Figure 2 Coefficient of atomic self-diffusion in solid neon: (●) from $T_{1\rho}$; (○) from T_2 . (Reproduced with permission from B. E. Sirovich and R. E. Norberg, *Phys. Rev. B.*, 1977, **15**, 5107)

3 KRYPTON

NMR measurements have been made^{18,19} on ^{83}Kr in both krypton of normal 11.55% abundance and isotopically enriched to 73.1% ^{83}Kr . Low-frequency (1.55 MHz) measurements¹⁹ were in a more homogeneous static field, which permitted ADRF measurements, even at normal abundance. Motional narrowing of the central $\frac{1}{2} \rightleftharpoons -\frac{1}{2}$ line terminated at $T_2 = T_1/6.25$. The effects of intraspin cross relaxation⁸ in the presence of a large first-order quadrupole interaction predict a $T_1/6.25$ factor as a limit for spin $\frac{9}{2}$ in the presence of an independent quadrupolar T_1 process such as the thermal phonon-quadrupole mechanism present in krypton. Inclusion of the intraspin cross-relaxation effect increases the useful range of motionally-narrowed central T_{2c} data by two orders of magnitude. The krypton diffusion experiments were extended¹⁹ to much lower temperatures and to ultraslow motions by means of spin lock and ADRF $T_{1\rho}$ measurements on both the central and noncentral components of the ^{83}Kr line in solid krypton. Figure 3 summarizes some of the relaxation rates for a reasonably clean (35 ppm N_2) krypton sample.

Figure 3 shows the spin-lattice relaxation rates R_1 for the whole line, central and noncentral widths R_{2c} and R_{2q} , and central and noncentral rotating frame rates $R_{1\rho c}$ (ADRF) and $R_{1\rho q}$ (ADRF). On the left of the figure, the motionally-narrowed R_{2c} rates limit in the warm solid at $6.25R_1$, where the $R_{1\rho q}$ (ADRF) rates limit at $4.0R_1$. Near $10^3/T = 11.8$

Figure 3 Summary of some of the ^{83}Kr nuclear spin relaxation rates observed in a solid krypton sample N (35 ppm N_2). Sloping lines indicate the deduced characteristic frequencies for atomic (ω_a) and vacancy (ω_v) motion. The curved solid line is $4R_1$. (Reproduced with permission from E. I. Madras and R. E. Norberg, *Phys. Rev. B.*, 1986, **33**, 5999)

the narrowing of R_{2c} shows a significant offset, which is examined in more detail in Figure 4. The offset is a ($l = \frac{9}{2}$) multiplicative factor of 5.96, predicted⁸ for R_{2c} at the onset of the effect of quadrupolar intraspin cross relaxation on the motionally narrowed dipolar interaction as the atomic hopping frequency (ω_a in Figure 3) becomes larger than the residual static quadrupole frequency $\omega_q = R_{2q}$. The correction is essential in order to infer the correct $l = 1, m = 1$ decay rate $R_{1,1} = (T_2)^{-1}$. The inverted triangles in Figure 4 represent $6.25R_1$, demonstrating excellent agreement with the R_{2c} data near the melting point. Correct diffusional analysis of the R_{2c} results¹⁹ involves: use of equation (2) in order to include data near $10^3/T = 13$; use of equation (5) for the case of the weak collision limit¹² of correlated motion on a f.c.c. lattice; and the intraspin cross relaxation 5.96 offset and $6.25R_1$ correction.⁸ Combination of the analyzed temperature variations of R_{2c} , $R_{1\rho}$ (spin lock), and $R_{1\rho}$ (ADRf) yields the coefficient of atomic self-diffusion in clean solid krypton (Figure 5). Here, as in neon, the quadrupolar correlation factor p_q was found to be unity. The line in Figure 5 shows the least-squares fit which corresponds to

$$D_0 = 8.7^{+3.0}_{-2.2} \text{ cm}^2 \text{ s}^{-1}, \quad E_d = 2612 \pm 25 \text{ K} \quad (12)$$

A resolvable contribution to the temperature variation of R_{2q} between 80 and 108 K (Figure 3) provides a direct NMR measure¹⁹ of the energy difference $E_M - E_F = 654 \pm 50 \text{ K}$. This result, combined with equation (12), $E_D = E_M + E_F = 2612 \pm 25 \text{ K}$, yields an NMR measure of the monovacancy mobility and formation energies in solid krypton:

$$E_M = 1633 \pm 38 \text{ K} \quad (13)$$

$$E_F = 978 \pm 38 \text{ K} \quad (14)$$

The E_F result is in reasonable agreement with the formation energies reported¹ by Losee and Simmons⁵ ($896 \pm 100 \text{ K}$)

Figure 4 Krypton sample N central component rates R_{2c} . (●) Exponential spin echo rates. (Δ, ○) Exponential and Gaussian free induction decay rates. A multiplicative 5.96 offset occurs near $10^3/T = 11.8$ where ω_a passes through ω_q . (▽) Warm sample R_1 data of Figure 3, each multiplied by 6.25. (Reproduced with permission from E. I. Madras and R. E. Norberg, *Phys. Rev. B.*, 1986, **33**, 5999)

and by Korpium and Coufal⁶ ($956 \pm 100 \text{ K}$). The NMR detection of vacancy motion occurs because, in the regime where the concentration of thermal vacancies ranges from 10^{-4} to 10^{-3} , an asymmetric R_{2q} relaxation peak occurs^{20–22} as the characteristic vacancy hopping rate becomes equal to twice the strength of the ^{83}Kr –vacancy quadrupole interaction. In the Arrhenius approximation, the high temperature side of the R_{2q} peak has a slope $E_M - E_F$.

The addition of 190–4000 ppm N_2 impurity produced¹⁹ increased rates R_1 and R_{2c} , to above 90 K. This additional relaxation arises from ^{83}Kr quadrupolar interaction with the electric field gradients of codiffusing impurities. The additional relaxation shows an Arrhenius behavior with an activation energy of 2214 K. The added impurities also increase the magnitude of quadrupolar $R_{1\rho}$ peaks near 90 K (Figure 3) and this additional relaxation is again consistent with 2214 K for the N_2 codiffusion.

4 XENON

Both ^{129}Xe and ^{131}Xe have been examined^{23,24} in solid xenon of natural abundance (26.24 at.% ^{129}Xe and 21.24 at.% ^{131}Xe). The spin- $\frac{1}{2}$ ^{129}Xe dipolar-broadened line narrows exponentially over more than three orders of magnitude

Figure 5 Coefficient of atomic self-diffusion in solid krypton. (Reproduced with permission from E. I. Madras and R. E. Norberg, *Phys. Rev. B.*, 1986, **33**, 5999)

between 117 K and the 161 K triple point. Figure 6 shows Carr–Purcell echo envelope T_2 values, which reflect exponential envelope decays above 125 K. Analysis of the adiabatic narrowing, including correlation effects and diffusion on a f.c.c. space lattice employs equations (4) and (5). The dipolar second moment arises 86.4% from like-spin 129–129 interaction and 13.5% from 129–131 unlike-spin interaction. The T_2 data in Figure 6 yield^{18,23} the following xenon diffusion coefficients:

$$D_0 = 9.7^{+0.5}_{-0.3} \text{ cm}^2 \text{ s}^{-1}, E_0 = 3724 \pm 25 \text{ K} \quad (15)$$

It is notable in Figure 6 that there is no evident deviation from an Arrhenius-described monovacancy diffusion mechanism, even in the vicinity of the triple point.

Measurements on ^{131}Xe in xenon of natural abundance showed²⁴ a central transition line that was appreciably second-order quadrupole broadened by interaction with remote defects in the rigid lattice. The onset and progression of motional narrowing agreed with the ^{129}Xe diffusion coefficient results of equation (15).

5 SELF-DIFFUSION IN RARE GAS SOLIDS

Table 1 lists the best value NMR-determined self-diffusion coefficients for neon, krypton, and xenon. Radioactive tracer results also are listed for argon and krypton. The activation energies for self-diffusion are nearly twice the lattice sublimation energies. Thus, E_D in rare gas solids is nearly the same as the work required to remove a single atom from the lattice to infinity.

Application of the law of corresponding states to an examination of the properties of neon presents the interesting question of the effects of an appreciable deviation from classical behavior. Table 2 summarizes a set of molecular parameters ϵ and σ appropriate for a Lennard–Jones (6–12) interatomic two-body potential and the deBoer quantum parameter [$\Lambda^* = h/\sigma (me)^{1/2}$] for the rare gases.²⁵

According to the classical law of corresponding states, the lattice cohesive energies and the activation energies for self-diffusion have the reduced forms $L_0^* = L_0/\epsilon$ and $E_D^* = E_D/\epsilon$, respectively. As Table 2 indicates, E_D^* and $2L_0^*$ vary by less than 5% among Ar, Kr, and Xe, but are some 20% smaller in Ne.

Bernardes²⁶ applied a quantum mechanical law of corresponding states to the description of the effects of zero point motion on the properties of rare gas solids. His results include a variation with the deBoer quantum parameter of the reduced

Figure 7 Variation of reduced activation energies as a function of the deBoer quantum parameter Λ^* . (●) Reduced latent heats of sublimation (L^*/L_{00}^*); (○, △) reduced diffusion energies ($E^*/D/2L_{00}^*$). (Modified from Henry and Norberg⁹)

lattice cohesive energies, according to the approximate expression

$$L_0^* = L_{00}^* (1 - 0.601\Lambda^* + 0.203\Lambda^{*2}) \quad (16)$$

where $L_{00}^* = 8.61$ is the classical reduced cohesive energy for a close-packed solid having no zero-point energy. Table 2 includes the quantities $E_D^*/2L_{00}^*$ and L_{00}^*/L_{00}^* , which are also plotted as a function of Λ^* in Figure 7 (which corresponds to Figure 2 in Bernardes' paper²⁶). The line indicated in Figure 7 corresponds to equation (16) and one sees that the quantum mechanical modification of the law of corresponding states accounts very well for the variation in the observed diffusion activation energies among the rare gas solids.

6 HYDROGEN IN RARE GAS SOLIDS

Conradi et al.²⁷ performed novel relaxation studies of dilute *o*-H₂ distributed in rare gas solids. The object of the experiments was to examine spin-lattice relaxation for the matrix-isolated *o*-H₂ molecules. In the course of the work it was found that the proton transverse rate T_2^{-1} contained both intermolecular and molecular-host contributions which

Figure 8 Temperature variation of the proton intermolecular T_2 for 52 ppm *o*-H₂ in solid neon. (○) FID; (△) spin echo; (●) T_2 results for ²¹Ne from Figure 1 for comparison. (Reproduced with permission from M. S. Conradi, K. Luszczynski, and R. E. Norberg, *Phys. Rev.*, 1979, **20**, 2594)

were narrowed out as diffusion set into the warm rare gas solids. Figures 8 and 9 compare the motional narrowing of the *o*-H₂ proton line with narrowing of the ²¹Ne and ⁸³Kr lines by self-diffusion in solid neon and krypton (Figures 1 and 3). Similar results were observed for *o*-H₂ in solid argon. In each case the proton narrowing corresponds to a codiffusion coefficient approximately equal to the host self-diffusion coefficient. Evidently translational motion of the molecular hydrogen requires the adjacent presence of a thermal monovacancy in the rare gas host.

A similar lattice control of molecular hydrogen diffusion has been observed for dilute molecular HD in solid argon and krypton. Deuteron and proton T_1 times have been measured^{28–30} for these systems. Figure 10 shows HD deuteron T_1 data, which decrease with increasing temperature from very long times at low temperature (more than 10³ s

Figure 9 Motional narrowing of the proton line for ca. 300 ppm *o*-H₂ in warm solid krypton. (▲) Residual T_2 arising from H-⁸³Kr interactions; (▽) ⁸³Kr dipolar T_2 results (Figure 3). below 10 K). The decrease is dominated by the Boltzmann factor for the increasing population of the HD $J = 1$ rotational state (128 K above the $J = 0$ ground state).³⁰ Above 40 K in argon (and 65 K in krypton) a more rapid T_1 decrease occurs as the onset of appreciable rare gas host self-diffusion permits diffusion of the HD molecules which then lose their matrix isolation and begin to experience additional spin-lattice relaxation via intermolecular interactions. As in the case of *o*-H₂, the warm-sample temperature relaxation time variations in Figure 10 are well fitted by the host self-diffusion coefficients.

1 INTRODUCTION

Soon after the first observations^{1,2} of nuclear magnetic resonance (NMR) in condensed matter it became clear that this new experiment had promising potential for the measurement and study of atomic transport. Two of the early questions asked about nuclear spin systems were: ‘How does a spin system reach the temperature of the surrounding “lattice”’, and ‘How long does it take to reach this thermal equilibrium?’. Here, the term ‘lattice’ is used to represent all the other degrees of freedom of the material, be it a solid or liquid, containing the spin system. In his phenomenological equations describing the interaction between the nuclear spins and applied static and time-dependent magnetic fields, Bloch³ identified the spin–lattice, or longitudinal, relaxation time T_1 , and the spin–spin, or transverse, relaxation time T_2 . In the presence of a large constant magnetic field, the difference between the instantaneous nuclear spin system’s magnetization and its equilibrium magnetization decays exponentially with the time constant T_1 , while T_2 is the time constant for exponential decay of the magnitude of the coherent component of the magnetization transverse to the large field.

Only 2 years after the publications of discovery of NMR, the first comprehensive description of the relationship between the nuclear spin relaxation rates and atomic motion came in the definitive paper of Bloembergen, Purcell, and Pound,⁴ which identified the relationship between the relaxation rates T_1^{-1} and T_2^{-1} and the modulation of the nuclear dipolar interactions caused by diffusive motion. They showed that each rate could be expressed by a linear combination of spectral density functions evaluated, for like nuclei, at the Larmor frequency and at twice that frequency. Each such function was expressed as the Fourier transform of pair correlation functions for interacting nuclear dipole moments. There are two distinct classifications of NMR experiments used to measure fundamental parameters of translational diffusion of atoms or molecules in solids; both are associated with spin system relaxation times.

The first technique is the measurement of the dependence of relaxation times upon temperature and the Larmor precession frequency. These measurements may be analyzed to yield

the temperature dependence of the mean residence time τ_d of the diffusing entity on a lattice site. The second is the measurement at one temperature of the attenuation of the spin echo in the presence of applied magnetic field gradients, from which the tracer diffusion coefficient D is deduced. The first method relies on having good theoretical understanding of the relationship between the mean residence time, the Larmor frequency and the measured relaxation time. The second technique is simpler theoretically, since it relies only on the assumption that the solution to the diffusion equation holds for the spin system, and it yields the diffusion coefficient directly. A disadvantage of the second technique is that it is more difficult and limited experimentally. It also requires higher diffusivity than does the measurement of some relaxation times.

This use of NMR to measure D directly was suggested by Hahn.⁵ Some kind of atomic or molecular label is needed to measure the diffusion coefficient. In Hahn’s proposal, the atom’s position along a particular direction was effectively labeled by making its Larmor frequency linearly dependent upon position through application of a uniform gradient of the magnitude of the applied magnetic field. With a very small gradient, the precession frequency of each spin is essentially constant. This constancy makes the spin echo^{5,6} experiments possible with echo attenuation limited only by the decay due to T_2 . When diffusion occurs in a sufficiently strong gradient, diffusive motion of each spin makes its precession frequency unpredictably time dependent, so that at the time of echo formation the accumulated disorder in the phases of spins in the transverse plane causes a spin echo attenuation given by⁶

$$S(t)/S(0) = \exp(-t/T_2 - \frac{1}{12}\gamma^2 G^2 t^3 D) \quad (1)$$

where γ is the nuclear magnetogyric ratio, G is the magnitude of the applied magnetic field gradient, τ is the time between the first and second rf pulses, and $t = 2\tau$. Echo attenuation may be measured as a function of G , and the resulting data are analyzed to determine D . The measured D is the tracer diffusion coefficient because the effect of the applied magnetic field gradient is to produce a nearly zero gradient in the chemical potential of the atoms in the system. As noted by Carr and Purcell,⁶ ‘A more innocuous label would be difficult to imagine’.

In terms of the tracer correlation factor f_t ($0 < f_t \leq 1$) and the step length l , D for a crystalline solid is given by

$$D = f_t l^2 / 6\tau_d \quad (2)$$

From independent determinations of τ_d (from relaxation times) and D , the product, $f_t l^2$, can be determined and used to test models for diffusion paths in the solid. For such detailed study, accurate theory for the relationships between relaxation rates and mean residence times are needed and have been calculated for common crystal structures. With these tools at hand, step lengths have been determined, and mixed monovacancy and divacancy diffusion mechanisms and effects of interactions between diffusing atoms have been identified; these topics are discussed below. Sophisticated pulsed gradient techniques have greatly extended the possibilities for measuring D in solids, and some of their applications are presented.

This review is presented in three parts, with the use of relaxation rates in Section 2, measurements of D in Section 3, and applications of these two in Section 4.

2 SPIN RELAXATION AND DIFFUSION

2.1 Introduction

Bloembergen, Purcell, and Pound⁴ (BPP) identified the nuclear dipolar coupling as a strong interaction for inducing spin relaxation. The interaction between two nuclear moments having spins I and S ,

$$\hat{\mathcal{H}}_D = \frac{\hbar^2 \gamma_I \gamma_S}{r_{IS}^3} \left[\hat{\mathbf{I}} \cdot \hat{\mathbf{S}} - \frac{3(\hat{\mathbf{I}} \cdot \mathbf{r}_{IS})(\hat{\mathbf{S}} \cdot \mathbf{r}_{IS})}{r_{IS}^2} \right] \quad (3)$$

varies in time as the internuclear vector $\mathbf{r}_{IS}$ changes because of the diffusive motion of one or both atoms. BPP described how that motion produced Fourier components of fluctuating dipolar fields at the precession frequencies and their sum and difference frequencies needed to induce spin transitions of one or both spins. Transitions in which both spins flip or one spin flips are driven by the raising and lowering operators $\hat{I}^+$, $\hat{I}^-$, S^+ , or S^- , implicitly contained in equation (3). Therefore, Fourier components which drive spin lattice relaxation of the I spin system are ω_{0I} , $2\omega_{0I}$, $(\omega_{0I} + \omega_{0S})$, and $(\omega_{0I} - \omega_{0S})$, where ω_{0I} and ω_{0S} are the resonant frequencies of the I and S spin systems, respectively. General theory of spin system relaxation is available.^{7,8}

For nuclei with $I > \frac{1}{2}$, the nuclear electric quadrupole interaction may, for the same reasons, be an effective relaxation mechanism. Here, atomic motion modulates the electric field gradient,⁹ and in some circumstances, the quadrupolar mechanism is stronger than magnetic dipolar relaxation. However, for measuring parameters of diffusion, utilization of the dipolar mechanism is, when possible, usually preferred because of high uncertainties in the knowledge of electric field gradients in the solid of interest.

As noted above, for accurate analysis of relaxation data, what is needed are accurate calculations, specific to each crystal structure, that relate relaxation rates to a characteristic diffusion parameter, i.e. the mean residence time of the diffusing atom on a crystal site. Relaxation rate theories are calculated in the weak or the strong collision regime. In the strong collision regime, the dipolar correlation time τ_d is greater than the thermal mixing time τ_m for the spin system. τ_m is the characteristic time needed for the Zeeman spin reservoir to come to a common spin temperature with the dipole spin reservoir.¹⁰ This process requires that the Zeeman field be smaller than characteristic dipolar fields, which is a relevant issue in the rotating coordinate system. The book by Goldman¹¹ treats the spin temperature concept in detail. Comments on strong collision experiments are reserved here until after the presentation of weak collision theory.

Weak collision theory applies when the Zeeman field is much larger than the characteristic dipolar field. In this regime $\tau_d \ll \tau_m$. This theory applies to many spin systems and temperatures where (depending upon the magnitude of γ) $\tau_d < 10^{-5}$ s, but strong collision theory extends to slower motion where 10^{-5} s $< \tau_d < 10^{-1}$ s.

2.2 Weak Collision Theory

The spectral density functions are defined by^{7,8}

$$J^{(q)}(\omega) = 2 \int_0^\infty G^{(q)}(t) \cos(\omega t) dt \quad (4)$$

where $G^{(q)}(t)$ is an ensemble average correlation function for the spatial coordinates of the dipolar interaction, and

$$G^{(q)}(t) = \sum_j \overline{F_{ij}^{(q)}(0) F_{ij}^{(q)*}(t)} \quad (5)$$

where the bar indicates the ensemble average. The functions $F_{ij}^{(q)}(t) = d_q Y_{2q}(\Omega_{ij})/r_{ij}^3$ are the dipolar interactions between spins i and j separated by $(r, \Omega)_{ij}$ at time t , and where $Y_{2q}(\Omega)$ are the normalized spherical harmonics having the z axis along the applied magnetic field, $\mathbf{B}_0$. The d factors are: $d_0^2 = (16\pi/5)$, $d_1^2 = (8\pi/15)$, and $d_2^2 = (32\pi/15)$. The spin operators have been incorporated in the expressions for the relaxation rates,^{7,12,13} given here for identical (like) spins:

$$\frac{1}{T_1} = R_1 = \frac{3}{2} \gamma^4 \hbar^2 I(I+1) [J^{(1)}(\omega_0) + J^{(2)}(2\omega_0)] \quad (6)$$

$$\frac{1}{T_{1\rho}} = R_{1\rho} = \frac{3}{8} \gamma^4 \hbar^2 I(I+1) \times [J^{(0)}(2\omega_1) + 10J^{(1)}(\omega_0) + J^{(2)}(2\omega_0)] \quad (7)$$

$$\frac{1}{T_2} = R_2 = \frac{3}{8} \gamma^4 \hbar^2 I(I+1) \times [J^{(0)}(0) + 10J^{(1)}(\omega_0) + J^{(2)}(2\omega_0)] \quad (8)$$

where $T_{1\rho}$ is the spin-lattice relaxation time in the rotating frame¹² and ω_1 is the precession frequency in the rotating field $\mathbf{B}_1$. The correlation functions are given by:¹⁴

$$G^{(q)}(t) = d_q^2 \sum_{\alpha, \beta} \frac{Y_{2q}^*(\Omega_\alpha)^*}{r_\alpha^3} \frac{Y_{2q}(\Omega_\beta)}{r_\beta^3} P(\mathbf{r}_\alpha, \mathbf{r}_\beta, t) \quad (9)$$

where $P(\mathbf{r}_\alpha, \mathbf{r}_\beta, t)$ is the probability of a pair of spins being separated by $\mathbf{r}_\beta$ at a time t given that they were separated by $\mathbf{r}_\alpha$ at time zero, and $P(\mathbf{r}_\alpha, \mathbf{r}_\beta, t)$ is determined by the diffusive motion in the solid. The correlation function decays with a characteristic time τ_c , which for translational diffusion should be approximately the mean residence time. The above expressions apply directly to a single crystal, but can also be averaged over all orientation angles for polycrystalline samples.

It is convenient to express the spherically averaged rates in terms of a single dimensionless spectral function $F(\omega\tau_c)$, which applies to any spin transition (parameter q). Equations (6)–(8) then become (for like spins only):

$$\frac{1}{T_1} = R_1 = \frac{2}{3} M_{II}^2 \tau_c [F(\omega_0\tau_c) + 4F(2\omega_0\tau_c)] \quad (10)$$

$$\frac{1}{T_{1\rho}} = R_{1\rho} = \frac{1}{3}M_{II}^2\tau_c[3F(\omega_1\tau_c) + 5F(\omega_0\tau_c) + 2F(2\omega_0\tau_c)] \quad (11)$$

$$\frac{1}{T_2} = R_2 = \frac{1}{3}M_{II}^2\tau_c[3F(0) + 5F(\omega_0\tau_c) + 2F(2\omega_0\tau_c)] \quad (12)$$

where

$$M_{II}^2 = (\mu_0/4\pi)^2 \gamma^4 \hbar^2 I(I+1) \sum_i r_i^{-6} \quad (13)$$

is, here, the dipole second moment for like spin interactions only.

2.2.1 The BPP Model

A simple assumption of an exponential decay was made by BPP for $G^{(q)}(t)$:

$$G^{(q)}(t) = G^{(q)}(0) \exp\left(-\frac{t}{\tau_c}\right) \quad (14)$$

It follows that the spectral density has the form

$$J^{(q)}(\omega) = \frac{G^{(q)}(0)2\tau_c}{[1 + (\omega\tau_c)^2]} \quad (15)$$

Torrey¹⁵ pointed out that, for like spins, the *relative* motion of spins contributes to the decay of $G^{(q)}(t)$, and therefore $\tau_c = \tau_d/2$. The relatively simple BPP form of $J^{(q)}(\omega)$ has made it a very useful, though approximate, model for analysis of data. In the low frequency, or short correlation time, regime ($\omega\tau_d \ll 1$), $J^{(q)}(\omega)$ is essentially independent of frequency, and for like spins $J^{(q)}(\omega) \approx G^{(q)}(0)\tau_d[1 - (\omega\tau_d/2)^2]$. At high frequencies, or long correlation times $\omega\tau_d \gg 1$, and again for like spins, $J^{(q)} \approx 4G^{(q)}(0)/(\omega^2\tau_d)$.

The low-frequency behavior of the BPP model is inconsistent with the solution to the diffusion equation when applied to calculation of $J^{(q)}(\omega)$, which for solids¹⁶ or liquids¹⁷ is

$$J^{(q)}(\omega) \approx J^{(q)}(0)[1 - c_1\omega^{1/2}] \quad (16)$$

where $J^{(q)}(0) \propto \tau_d$ and c_1 is a constant, different for solids than for liquids. In fact, c_1 specifically depends on D , so that in principle D could be determined from the frequency dependence of $J^{(q)}(\omega)$ in the short correlation time regime.¹⁶ [For two-dimensional diffusion¹⁶ there is a much stronger frequency dependence at $\omega\tau_d \ll 1$. Here, $J^{(q)}(\omega) \approx c_2\tau_d \ln(\omega)^{-1}$, where c_2 is dependent upon D and the structure of the solid.] In the very low and high frequency limits, accurate calculations show that $J^{(q)}(\omega)$ is proportional to τ_d and to $(\omega^2\tau_d)^{-1}$, respectively, as in the BPP model, but the constants of proportionality in the BPP model can be in error^{16,18} by up to a factor of 3. For thermally activated diffusion $\tau_d = \tau_0 \exp(E_a/RT)$, where E_a is the activation energy (per mole) for diffusion. It is usually convenient experimentally to hold the NMR frequency constant and vary the temperature. In such an experiment a graph of the relaxation rate, R_1 versus $(1/T)$, would have slope $+(E_a/R)$ at very high temperatures and

Figure 1 Relaxation rate (in arbitrary units) as a function of $\omega_0\tau_d$ for R_1 , $R_{1\rho}$ and R_2 in the BPP model with $\omega_0 = 500 \omega_1$

$-(E_a/R)$ at low temperatures. On such a graph the maximum of R_1 in the BPP model occurs for a system of like spins, at $(\omega\tau_d) = 1.23$. Although the BPP model is an approximation and not specific to any crystal lattice, it is highly regarded for its ease in applicability and its utility. It is seen in the next section that the errors noted above may be significantly reduced if it is assumed that for like spins $\tau_c = \tau_d$. The dependences of R_1 , $R_{1\rho}$, and R_2 , upon $\omega\tau_d$ in the BPP model are shown in Figure 1. On the low-temperature side of the peak in R_1 , the transverse rate, $R_2 \propto \tau_d$. Using this relationship, Hultsch and Barnes¹⁹ measured the pressure dependence of T_2 of ^7Li and ^{23}Na in solid lithium and sodium, respectively, and determined the activation volumes for self-diffusion in these solids.

2.2.2 Lattice-Specific Models

In many solids, translational diffusion is enabled by vacancies, (empty lattice sites) in the solid. Only atoms next to a site vacancy can move. For most solids, vacancies must be thermally activated. Typically, vacancy concentrations are very small, increase strongly with temperature, but reach fractional concentrations of only about 10^{-4} to 10^{-3} near the melting point. When a vacancy encounters an atom the atom can move, but its motion during the encounter is not random in that it has a significant probability of jumping back to take the place of a vacancy immediately after it has exchanged sites with it. The effect of this correlated motion²⁰ on the NMR spectral density is distinguishable from an uncorrelated random walk process that would occur with low atom concentration on an otherwise empty lattice. The interstitialcy mechanism has also been considered in lattice-specific calculations.

High vacancy concentrations are characteristic of a number of systems, such as hydrogen in metals and fast ionic conductors. For example, in the α' phase of the VH_x , NbH_x , and TaH_x systems, hydrogen atoms occupy the tetrahedral interstitial sites and the solubility of hydrogen atoms in this phase ranges from $x = 0$ to about 0.7, depending on the host metal. Therefore, there is interest in knowing $J^{(q)}(\omega, \tau_d)$ for the full range of atomic concentration, c . Figure 2 shows a plot

Figure 2 Angular average of the spin-lattice relaxation rate (in arbitrary units), divided by c , as a function of $y = \omega_0\tau_d/2$ for like spins on the simple cubic lattice. (---) The BPP model. (—) Lattice-specific models for atom concentrations, from left to right: $c \rightarrow 1$, 0.99, 0.90, 0.70, 0.50, and $c \rightarrow 0$, respectively. of R_1 versus $(\omega\tau_d/2)$ calculated from lattice-specific models¹⁴ for the simple cubic lattice. It can be seen in Figure 2 that letting $\tau_c = \tau_d$ in the BPP model moves the BPP curve a factor of 2 to the left and into better agreement with the others. Many calculations of $J^{(q)}(\omega, \tau_d)$ must be done numerically.

The relationships between relaxation rates and the mean residence time, τ_d have been calculated specifically for the more common crystal structures, for example: simple cubic (s.c.); body-centered cubic (b.c.c.); and face-centered cubic (f.c.c.). These relationships do indeed differ perceptibly from one lattice to another. It is known that the dependence of R_1 upon τ_d for a given lattice changes with the microscopic diffusion mechanism, but that these differences are small. Measurements of high precision on spin systems with very well understood relaxation mechanisms are needed before one can hope to use experimental data to rule out a contending microscopic mechanism.

The first lattice-specific relaxation rate theoretical calculations for R_1 and R_2 were made by Torrey¹⁵ and Resing and Torrey.²¹ In these calculations, nuclear dipoles were assumed to move by an uncorrelated random walk by nearest neighbor jumps through the lattice. The average of relaxation rates over all crystalline directions were approximated by the use of an isotropic diffusion model. Relaxation rates were calculated numerically for like spins only; their most accurate results are presented in Resing and Torrey²¹ in tabular form for the b.c.c. and f.c.c. lattices. At fixed frequency, R_1 reaches a maximum at $\omega\tau_d = 1.06$ and 1.04 for the f.c.c. and b.c.c. lattices, respectively. Because of the assumption of uncorrelated motion, these results would be expected to be applicable at low concentrations of atoms on a crystal lattice, or sublattice.

Before it appeared in print, the Torrey model was applied to analyze data in the first comprehensive set of pulsed NMR experiments²² measuring effects of diffusion on NMR relaxation rates in alkali metals. Holcomb and Norberg²² convincingly demonstrated the applicability of NMR to the study of diffusion in solids. Their most extensive data were

Figure 3 Plot of $\omega_0\tau_d/2$, where $\tau = \tau_d$, against $10^3/T$ for ^7Li in solid lithium. Values of τ were obtained from analysis of R_1 data at 3 MHz using the Torrey theory. The slope is $13.2 \text{ kcal mol}^{-1} = 55.2 \text{ kJ mol}^{-1}$. (Reproduced by permission of The American Physical Society from D. F. Holcomb and R. E. Norberg, *Phys. Rev.*, 1955, **98**, 1074)

from ^7Li with temperature dependence of T_1 measured at 3, 6, 9, and 15 MHz. ^7Li data at 3 MHz were analyzed by trying both the BPP and the Torrey theory. The better fit to the data, shown in Figure 3 came from Torrey theory for the b.c.c. lattice, and from it they found that $E_a = 55.2 \pm 2 \text{ kJ mol}^{-1}$.

Sholl^{23,24} and Wolf²⁵ addressed the random walk problem without the approximation of isotropic diffusion. Both took the discrete nature of the lattice into account for both single and polycrystalline materials. The papers of Barton and Sholl,²⁶ provide good perspective on the random walk model and include tables that conveniently allow calculation of R_1 , $R_{1\rho}$, or R_2 , for any product of $\omega\tau_d$ in s.c., b.c.c., or f.c.c. lattices. These improved calculations have, for like spins in a polycrystalline sample, the maximum in R_1 occurring at $\omega\tau_d = 1.04$, 0.99, and 0.92 for f.c.c., b.c.c., and s.c. lattices, respectively.

While few real systems were expected to have atoms diffusing by random walk, these lattice-specific calculations were still important in the development of the theory. The shape of the R_1 versus τ_d curve for random walk fit the data better than the shape of the BPP curve did. A second improvement to the random walk came with the mean field model²⁷ which accounted for the effects of site blocking. That is, it excluded the possibility of having two atoms on the same site. The mean field theory is exact where a single jump for a pair of spins is relevant, in the low-temperature (high-frequency) limit, except where the fractional atom concentration is $c \rightarrow 1$. It is also exact in the dilute

limit as $c \rightarrow 0$, and the model was expected to be a good approximation for most concentrations except²⁶ as $c \rightarrow 1$. In the mean field model, for like spins in a polycrystalline sample, the maximum in R_1 occurs at $\omega\tau_d = 0.95, 0.89$, and 0.77 for f.c.c., b.c.c., and s.c. lattices, respectively.

2.2.3 Monovacancy Diffusion

Diffusion enabled by vacancies at extremely low concentration is known as ‘monovacancy diffusion’. Wolf²⁸ provided the first relaxation rate theory applicable to this mechanism. At their characteristically low concentration, vacancies move with random walk and atoms are displaced only through encounters with vacancies. Eisenstadt and Redfield²⁹ identified the encounter model and its role in NMR relaxation in their study of diffusion in ionic crystals.

Wolf³⁰ calculated relaxation rates in the encounter model for both the weak and strong collision regimes, and he identified characteristic features of temperature-dependent experimental data that could, in principle, be applied to identify microscopic diffusion mechanisms. He emphasized the valuable information contained in the anisotropy of relaxation rates,^{28,30,32} especially $R_{1\rho}$, for single crystal samples. For polycrystalline or single crystal samples, Wolf et al.³² defined measures of the width and asymmetry of the relaxation peak that were dependent upon the mechanism of diffusion.

A comprehensive series of experiments were performed by Figueroa and Strange and reported with Wolf^{32,33} on the NMR of ^{19}F in pure BaF_2 and crystals doped with K^+ to control F^- vacancy concentrations, or with La^+ to control number of interstitial F^- . This element of control made it possible to determine the activation energies for migration of F^- by vacancies ($E_{\text{mv}} = 59 \text{ kJ mol}^{-1}$) and by interstitials ($E_{\text{mi}} = 74 \text{ kJ mol}^{-1}$). From the pure BaF_2 data (Figure 4), the energy of formation of Frenkel anion pairs ($E_{\text{f}} = 174 \text{ kJ mol}^{-1}$) was determined. Comparison with conductivity data³⁴ showed satisfactory agreement with diffusion parameters obtained by the two techniques. In their analysis of the NMR data, there was clear agreement with the encounter model but not the random walk model. Even though the data appear to have little scatter, especially considering the very high temperatures at which much of it was recorded, the difference between the interstitialcy and monovacancy mechanisms could not be distinguished.

Building upon previous calculations on relaxation rate theory,^{16,35} MacGillivray and Sholl³⁶ improved the accuracy of the encounter model in the monovacancy limit to better than 4% and 1% in the low- and high-frequency regimes, respectively. Their paper contains numerical tables from which spectral densities $J^{(q)}(\omega, \tau_d)$ can conveniently be calculated for s.c., b.c.c., and f.c.c. lattices. From these, more accurate predictions of the width and asymmetry of relaxation rate peaks can be made. In the monovacancy limit, the peaks in the spin-lattice relaxation rate R_1 for like spins occur at³⁵ $\omega\tau_d = 0.57, 0.51$, and 0.42 for the f.c.c., b.c.c., and s.c. lattices, respectively. All these peaks in R_1 occur at significantly lower values of $\omega\tau_d$ than in the random walk or the mean field models. This means that if NMR data for R_1 or $R_{1\rho}$ from a solid having monovacancy diffusion were analyzed with the random walk, mean field, or the BPP models, the deduced τ_d at temperatures near maximum relaxation rates would be too large by at least 67% for the first two, and by more than

Figure 4 Relaxation times plotted against $10^3/T$ for ^{19}F in a pure BaF_2 single crystal. ($\square$) T_1 taken at 10 MHz; ($\circ$, $\bullet$, Δ) $T_{1\rho}$, $B_1 = 1.2 \times 10^{-3} \text{ T}$, for three different crystal orientations; ($\blacktriangle$) $T_{1\text{Dipolar}}$; ($\blacksquare$) T_2 . Details on crystal orientations may be found in Figueroa et al.³³ (Reproduced by permission of The American Physical Society from D. R. Figueroa, J. H. Strange, and D. Wolf, *Phys. Rev. B*, 1979, **19**, 148)

100% for the BPP model. But the error in the activation energy would probably be very small for the first two models because they give essentially the same shape for the relaxation peaks. However, since the peak is narrower in the BPP model, the activation energy derived from its use could be systematically too small by an amount that depends upon the range of temperature over which data were available (see Section 2.2.5).

2.2.4 Models for Arbitrary Concentrations

In 1978, Fedders and Sankey¹⁸ published their multiple scattering theory for the s.c. lattice using a reciprocal space formalism that can be applied to any concentration from $c = 0$ to nearly the monovacancy limit. They published their numerical results for the spectral densities in the low- and high-frequency limits for $c = 0$ to $c \rightarrow 1$ in steps of $\Delta c = 0.2$. While they gave no numerical tables for the spectral densities at arbitrary $\omega\tau_d$, they offered to supply tables of T_1 versus $\omega\tau_d$ upon request. It is pointed out that the lattice-specific relaxation function (Figure 5) approaches its high- and low-temperature limits more gradually than the BPP model does. Results for the f.c.c. lattice were reported in a later paper.³⁷ An interesting product of their formalism is a simple analytic

Figure 5 Angular average of spin-lattice relaxation time (in arbitrary units) for like spins on the s.c. lattice as a function of $\omega_0\tau_d$ calculated for the multiple scattering theory with atomic concentration $c = 0.85$. (---) Asymptotic limits for $\omega_0\tau_d$ sufficiently large and small; they show how gradually the curve approaches each line. (Reproduced by permission of The American Physical Society from P. A. Fedders and O. F. Sankey, *Phys. Rev. B*, 1978, **18**, 5938)

expression (accurate to about 1%) for the tracer correlation factor for atoms at concentration c in a simple cubic lattice:

$$f_t = 0.7882[1 + 0.1059(6c - 4)/(2 - c)] \quad (17)$$

Fedders³⁸ also considered the effect that interactions between mobile atoms would have on the dipolar relaxation mechanism. These interactions are more likely to be important in systems having intermediate concentrations of diffusing atoms (with number of vacancies exceeding 10% of the number of lattice sites), as in metal hydrides. At short distances, the H-H interaction is repulsive, and in some metals, (for example, the group V transition metals) it is sufficiently strong to prevent simultaneous occupation of nearest neighbor interstitial sites. In the BPP model, one would be tempted to compensate for this interaction by simply removing nearest neighbor terms from the lattice sums contained in calculating the second moment of the hydrogen spin system. Doing this underestimates the dipolar interaction strength in the low-frequency (high-temperature) regime because here the motions of atoms further from each other than the nearest neighbor positions are the most effective in inducing spin transitions. For this motion short-range repulsive reactions are irrelevant.³⁸ On the high-frequency (low-temperature) side of the relaxation rate peak, single steps of atoms account for the decay of the pair correlation function and the reduction of the second moment is a good approximation³⁸ to the effects of the above repulsive interaction.

2.2.5 Monte Carlo Simulations

For any crystal structure, the pair correlation functions $G^{(q)}(t, \tau_d)$ can be computed numerically by simulating motion with the Monte Carlo technique. Bustard³⁹ established an s.c. lattice having 8000 sites (20 lattice constants on each side) and assumed periodic boundary conditions. Using the Monte Carlo

Figure 6 Angular average of spin-lattice relaxation rates as a function of $\omega_0\tau_d$, as calculated for like spins from simple cubic lattice theories. ($\square$) Monovacancy encounter model;¹⁰ ($\bullet$) random walk model;²⁶ ($\triangle$) vacancy concentration, $c_v = 0.15$.¹⁸ (—) Monte Carlo for $c_v = 0.15$. (Reproduced by permission of The American Physical Society from L. D. Bustard, *Phys. Rev. B*, 1980, **22**, 1))

technique he calculated numerically T_1^{-1} versus $\omega\tau_d$ for like spins on this s.c. lattice with vacancy concentrations, $c_v = 3.75 \times 10^{-4}$, 0.15, 0.225, and 0.90, and published the appropriate tables for these concentrations. The Monte Carlo results are in substantial agreement with multiple scattering theory¹⁸ for $c_v = 0.15$ (Figure 6) and with mean field theory²⁶ for $c_v = 0.90$. A difficulty in the Monte Carlo calculations is their inaccuracy in the low-frequency regime. Bustard³⁹ dealt with this by making a least-squares fit to $G^{(q)}(t, \tau_d)$ with a sum of decaying exponentials. This substitution facilitated making the Fourier transform to $J^{(q)}(\omega, \tau_d)$ but, since the long time tails of the exponential decay curves decay faster than the actual¹⁶ $t^{-3/2}$ form of the tail of $G^{(q)}(t, \tau_d)$, Bustard's Monte Carlo magnitudes of R_1 and $R_{1\rho}$ were too small where $\omega\tau_d \ll 1$. Nevertheless, the calculations were accurate enough for R_1 data to be analyzed at two NMR frequencies in order to obtain the temperature dependences of τ_d for ^1H in $\text{TiH}_{1.55}$ and $\text{TiH}_{1.70}$, where $c_v = 0.225$ and 0.15 on the interstitial s.c. lattice, respectively. These results for τ_d were combined with direct NMR measurements⁴⁰ of the diffusion coefficient D using the pulsed field gradient technique in the stimulated echo experiment, so that the mean squared jump length l^2 could be determined from $D = f_t l^2 / (6\tau_d)$. It was found that hydrogen atoms jump to their nearest neighbor sites and not to their third nearest neighbor sites as had been found theoretically to be feasible.⁴¹ Similar sets of experiments have recently been done for the isomorphous system ZrH_x ,⁴² analyzing R_1 data with more recent Monte Carlo calculations⁴³ for τ_d , and reaching the same conclusion.

Faux et al.⁴³ made Monte Carlo calculations for like spins moving according to the simple hopping model on f.c.c., b.c.c. and s.c. lattices. They fitted their numerical calculations of $J^{(q)}(\omega, \tau_d)$ in the low- and high-frequency limiting cases to the corresponding expected frequency dependences calculated earlier by Sholl.¹⁶ This fitting also checked the accuracy of their Monte Carlo numerical procedures.⁴³ Numerical tables provide spectral densities and R_1 at many selected values of $\omega\tau_d$ for concentrations c approaching 0, 0.5, 0.7, 0.9, and 0.99. For $c \leq 0.4$, application of mean field theory might be an

acceptable and convenient approximation, since its difference from the Monte Carlo results is quite small.⁴³

Because use of numerical tables is not as convenient as an analytic expression (such as that for the BPP model) in fitting experimental data, analytic approximations to the numerical tables given by Faux et al.⁴³ for intermediate concentrations, by Barton and Sholl²⁶ for mean field theory, and by MacGillivray and Sholl³⁶ for monovacancy diffusion have been developed by Sholl.¹⁴ Faux et al.⁴³ and Sholl¹⁴ provide an overview of the dependences of the relaxation rates upon atom concentration on the f.c.c., b.c.c., and s.c. lattices from $c \rightarrow 0$ to $c \rightarrow 1$. Figure 2 shows R_1 versus $\omega\tau_d/2$ for the full range of concentration on a simple cubic lattice plotted from the analytic expressions given by Sholl¹⁴ and, for comparison, the BPP model. It is seen here, and is apparent for all cubic lattices, that the relaxation peak is narrower in the BPP model than for any concentration of the lattice-specific models. There is little concentration or model dependence in the maximum relaxation rates shown in Figure 2. For all the lattice-specific relaxation rate curves, their peaks are located at significantly lower values of $\omega\tau_d$ than for the BPP model (using $\tau_c = \tau_d/2$). It can be seen in Figure 7 that

Figure 7 The value of $(\omega_0\tau_d)_{\max}$ at the maximum of the R_1 versus $\omega\tau_d$ curve, plotted against atom concentration c for a polycrystalline b.c.c. lattice. The $(\omega_0\tau_d)_{\max}$ values are normalized to the mean field theory value of 0.89. The point at $c = 1$ is for the monovacancy limit. The bar is the estimated error of the Monte Carlo results. The points for the f.c.c. and s.c. lattices lie above and below these points, respectively. On this graph, the points for the BPP model would be at 1.38, independent of c . (Reproduced by permission of IOP Publishing Ltd from D. A. Faux, D. K. Ross, and C. A. Sholl, *J. Phys. C: Solid State Phys.*, 1986, **19**, 4115)

Figure 8 (---) $\tau_d = \tau_{\text{BPP}}$, obtained by analyzing the R_1 relaxation results of the mean field theory using the BPP model. The horizontal axis shows τ_d in the mean field theory, and $(\omega_0\tau_d)_{\max}$ is approximately centered. The solid line has the 'correct' slope. In the limits of large and small τ_d , the two lines are parallel, but over the region shown, the average slope of the dashed line is seen to be the smaller one. (Reproduced by permission of Sci-Tech Publications from C. A. Sholl, *Diffus. Defect Data, Solid State Data A, Defect Diffus. Forum*, 1993, **95–98**, 91)

the value of $\omega\tau_d$ at the peak decreases monotonically from the $c = 0$ limit to the $c = 1$ limit, with most of the change coming between $c = 0.5$ and $c = 1.0$. Because the value of $\omega\tau_d$ at the peak may be used to set the absolute values of the determinations of τ_d from experimental R_1 data, Figure 2 is useful for estimating the relative error resulting from application of an inappropriate model. The activation energies determined by application of the BPP model should be accurate if there are experimental data extending far into the wings of the relaxation peak. However, often the data are most accurate or only available near the peak where there is relatively less competition from other relaxation mechanisms. In this regime, the narrowness of the peak in the BPP model means that if it were used to analyze data obtained with a lattice-specific model, the resulting values of τ_d (shown as τ_{BPP} in Figure 8) might be interpreted in terms of an activation energy that would be too small. The resulting systematic error in E_a could exceed 10%.⁴⁴

2.2.6 Quadrupolar Relaxation Mechanisms

As noted earlier, nuclear electric quadrupolar interactions may be an effective mechanism for spin relaxation where the interaction is modulated by atomic motion. Its utilization for the study of diffusion is more complicated than the dipolar mechanism because: (1) the electric field gradient (EFG) might be unknown; and (2) the spin system's recovery might be multiexponential. Lack of knowledge of the magnitude of the EFG might be acceptable, since it mainly affects the magnitude of spin–lattice relaxation rates, but it might have a temperature dependence strong enough to complicate data interpretation. The recovery through spin–lattice relaxation will be a single exponential⁷ if the spin $I = 1$, if the motion is so fast that $\omega_0\tau_d \ll 1$, or if the dipolar interaction can maintain a spin temperature in the spin system.¹⁰ Otherwise, the recovery is the sum of exponentials the number of which depends upon I .⁴⁵ If the spin system has a static quadrupole interaction,

establishment of a spin temperature is unlikely outside of thermal equilibrium with the lattice.

Without a static quadrupole interaction, it is likely that the dipolar interactions within the spin system can maintain a spin temperature during recovery. If so, the recovery occurs with the relaxation rate^{7,10}

$$\frac{1}{T_{1Q}} = R_{1Q} = C_Q [J_Q^{(1)}(\omega_0) + J_Q^{(2)}(2\omega_0)] \quad (18)$$

where

$$C_Q = (9/160)(eQ/\hbar I)^2(2I + 3)/(2I - 1) \quad (19)$$

and the dynamic EFG is contained in the spectral densities, $J_Q^{(i)}(\omega_0)$. If the dynamic EFG is due to point charges, as in ionic compounds, the spectral densities will depend upon normalized spherical harmonics as do those for dipolar interactions. But the quadrupolar spectral densities may differ from the dipolar because of the potential importance of three particle correlation functions in many solids.⁴⁶ A difference in principle is that the $J_Q^{(2)}(2\omega_0)$ term in quadrupolar relaxation corresponds to $\Delta m = \pm 2$ of one spin, but in dipolar relaxation it means $\Delta m = \pm 1$ for a pair of spins. If a spin temperature is not maintained during recovery, the recovery is a combination of I exponentials for integral spins and $(I + \frac{1}{2})$ exponentials for half-integral spins.⁴⁵ For a system with a static quadrupole interaction, the mix of exponentials is expected to be similar to that with no static interaction except that the spectral density functions would have arguments different from ω_0 and $2\omega_0$. The mix would depend upon the initial conditions of the spin system at the start of the recovery as established by the rf pulse sequence used and the energy levels to which it was applied. Gordon and Hoch⁴⁵ present results for excitation of the central transition only.

Because of the uncertainties of the magnitude of the dynamic quadrupole interactions, and because static interactions often occur in the less common crystal structures and in disordered solids, very few lattice-specific calculations are available for data analysis. The BPP model is often applied to obtain numerical values of diffusion parameters from these experiments.

2.2.7 Disordered Solids

In disordered solids, such as alloys or glasses, it would be expected that each atom of a given type would have different probabilities for jumping in each of its likely jump directions because of different barrier heights and vibration frequencies. Also, there would be a distribution of site binding energies, and, ignoring other possible effects of the disorder, it is still not obvious how these variations would affect the temperature and frequency dependences of NMR relaxation rates.

It is commonly found experimentally that at fixed frequency, when the relaxation rate due to translational diffusion has been plotted against T^{-1} , the characteristic peak in the rate has a lower magnitude slope on the low-temperature side than on the high-temperature side. In systems where, for example, the mean squared dipolar interaction is known through independent measurement of the second moment of the NMR line, the maximum relaxation rate may be reduced from the rate estimated from the known second moment. These

characteristics may be emulated in the calculation of a mean relaxation rate for a distribution of activation energies where the dependence of R_1 upon E_a follows from its dependence upon τ_d and the Arrhenius relationship:

$$\tau_d = \tau_0 \exp(E_a/RT) \quad (20)$$

Assuming a distribution of activation energies, $g(E_a)$, the mean relaxation rate is

$$\left\langle \frac{1}{T_1} \right\rangle = \int g(E_a) R_1(E_a) d(E_a) \quad (21)$$

There are other models for NMR relaxation in disordered systems. Beckmann⁴⁷ has reviewed many and presented them in a format readily applied to NMR. The question for each is: what is the physical significance of the parameters that would be derived from a fit to NMR relaxation data? McDowell⁴⁸ has applied Monte Carlo techniques to solids disordered with distributions of site energies and, separately, with distributions of barrier height energies. He has found that in the Monte Carlo simulations the observed asymmetry of the relaxation peak occurs with the barrier height distribution but not with the site energy distribution.

The Kohlrausch–Williams–Watts (KWW) model⁴⁷ has seen considerable application. It produces the characteristic asymmetric shape of the relaxation peak and is known as the ‘stretched exponential’ for the form of its correlation function, which is proportional to $\exp[-(t/\tau^*)^{1-n}]$, where $n < 1$. Ngai and Martin⁴⁹ argue that at long times, decay of the correlation function is slowed down due to dynamic correlations among the atoms that arise from their mutual interactions.

Elliot’s diffusion controlled relaxation (DCR) model⁵⁰ has recently been applied to NMR in ionic conducting glasses.⁵¹ The transport mechanism involves the motion of interstitialcies followed by ionic relaxation in the vicinity of a recently arrived interstitial atom. The form of the correlation function can be viewed as a stretched exponential, but the power β to which the time t is raised would be itself time dependent.

No one model is expected to be applicable to all disordered systems, and more than one model might fit the data of one system. What remains to be seen is which models can be convincingly identified with the structure and dynamic processes in glasses. A good test of the applicability of a spin relaxation model is to compare its predictions of the diffusion coefficient of the mobile atom, based on relaxation rate measurements, to an independent set of measurements of D obtained from, for example, NMR pulsed field gradient measurements, or from electric conductivities, preferably in the same temperature range, although this cannot always be realized because of the limitations in measuring low values of D .

2.3 Strong Collision Theory and Experiments

The strong collision regime, defined by Slichter and Ailion,⁵² is characterized by fast thermal mixing between the dipolar and Zeeman energy reservoirs that meets the condition $\tau_m \ll \tau_c$, where τ_m is the mixing time, and $\tau_c = (\tau_d/2)$ for a system of like spins in the solid. This energy exchange cannot occur if $B_1 > B_{D\rho}$, where $B_{D\rho}$ is the measure of the

nuclear dipolar field in the rotating frame. At sufficiently low temperatures, $\tau_m^{-1} \approx \gamma B_{D\rho}$, so that the inequality, $\tau_m \ll \tau_c$ requires that the lattice temperature be below the motional narrowing temperature of the solid.⁸ Under these conditions, Slichter and Ailion find

$$R_{1\rho} = \frac{2(1-p)}{\tau_d} \frac{B_{D\rho}^2}{B_1^2 + B_{D\rho}^2} \quad (22)$$

where p is a parameter which represents the fact that the local field is not completely random after a single atom jump. The important concept in the strong collision regime is that the correlation time is essentially determined by single jumps. In the rotating frame experiment, the relatively high degree of order in the spin polarization, originally along the large applied field in the laboratory frame, becomes transferred to dipolar and Zeeman order in the rotating frame. This order is locally disrupted when an atom jumps to a neighboring site and may be gradually eroded by some other spin-lattice relaxation mechanism. The latter limits $T_{1\rho}$, which puts an upper limit on τ_d that is measurable. In the Slichter and Ailion experiment⁵³ on ^7Li in lithium metal, relaxation by conduction electrons limited observation to temperatures above about 190 K where $\tau_d \leq 1$ s, a very long time in translational diffusion. The values of τ_d obtained in this regime were found to be consistent with those found from T_1 measurements by Holcomb and Norberg.²²

The strong collision theory is lattice specific in that the parameter p must be carefully calculated for each lattice. In their experimental paper,⁵³ Slichter and Ailion derived p for the b.c.c. lattice and found $p = 0.2663$. Of course, $B_{D\rho}$ is also lattice dependent (see *Ultralow Motions in Solids*).

3 DIRECT MEASUREMENT OF DIFFUSION COEFFICIENTS USING MAGNETIC FIELD GRADIENTS

3.1 Introduction

Analysis of measurements of the temperature and frequency dependence of nuclear spin relaxation rates yields the temperature dependence of the mean residence time of atoms in the solid. For a known structure of the solid, and from an assumed or known mechanism of diffusion and its tracer correlation factor, D can be calculated using equation (2). But it is not necessary to rely upon theory to obtain D , because it is directly measurable with NMR from echo attenuation caused by application of uniform magnetic field gradients in a selected spin echo experiment. As noted in Section 1, the field gradient provides the label needed in the measurement of the tracer D . At a coordinate, $\mathbf{r}$, the precession frequency is given by $\omega(\mathbf{r}) = \gamma B_0 + \gamma \mathbf{G} \cdot \mathbf{r}$, where B_0 is the applied magnetic field, $\mathbf{G}$ is the applied gradient, and $\mathbf{G} = \nabla B_z$. Usually only the z component of ∇B_z is applied in measuring D , although the others might be used to measure diffusivity in directions normal to B_0 . (Unless otherwise stated, D is assumed to be isotropic.) In addition to the applied gradient, there is usually a background gradient $\mathbf{G}_0$, which includes the inhomogeneity of B_0 and constant gradients in the sample due to the sample material susceptibility and its shape.

3.2 Application of a Constant Field Gradient

Although it is possible through extraordinary measures to remove the dipolar interaction in solids with multiple pulse techniques, most diffusion measurements are made at temperatures where the dipolar interactions are motionally narrowed. For the Hahn spin echo, the echo attenuation for gradients constant in time, is given by⁶

$$S(t) = 2\tau/S(0) = \exp[-(2\tau/T_2) - \frac{2}{3}\gamma^2 D \tau^3 (\mathbf{G} + \mathbf{G}_0)^2] \quad (23)$$

where τ is the time between the $\pi/2$ and the π rf pulses. At a fixed echo time, the numerical value of D may be obtained from dependence of the echo attenuation upon the magnitude of $\mathbf{G}$. This method is relatively easy to implement especially in application to fluid samples where D is large. For example, for ^1H in water where $D \approx 2 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$, and $\tau = 30$ ms, $G \geq 2 \times 10^{-2} \text{ T m}^{-1}$ to attenuate the echo by a factor $1/e$, and it has been assumed that $G \gg G_0$. In solids, where D may be much smaller, considerably larger field gradients would be needed for acceptable echo attenuations.

The need for larger constant gradients presents two experimental problems, beyond the nontrivial ones of gradient coil design and coil cooling, which are: (1) the need for high rf power to provide the larger tipping field in the rotating coordinate system; and (2) the need for broader bandwidth, $\Delta\omega_{\text{rec}}$ for the rf receiver in the NMR spectrometer to accompany the broader spectrum of the spin system being observed. The NMR linewidth will be broadened by the gradient field by approximately $\Delta B \approx GR$, where R is the radius of the sample. Therefore, the tipping field B_1 must be increased as G is increased, and the rf power must increase as G^2 is increased. To avoid having the observed echo shape distorted, $\Delta\omega_{\text{rec}}$ must exceed the spectral width of the spin system observed. An increased $\Delta\omega_{\text{rec}}$ increases the noise observed with the echo and, therefore, reduces the signal-to-noise ratio and increases the accumulation time needed for an acceptable signal-to-noise ratio. These experimental problems are so severe that the constant gradient has not seen much use for solids.

3.3 Application of Pulsed Field Gradients

3.3.1 The Spin Echo Pulsed Field Gradient Experiment

The solution to these problems, turning off the field gradient during rf pulses and during signal accumulation, was proposed by Stejskal and Tanner in their definitive paper⁵⁴ describing the use of pulsed field gradients (PFGs) for the measurement of D . The timing of the gradient pulses in the spin echo experiment is shown in Figure 9 where a gradient pulse of amplitude $\mathbf{G}$ is applied at a time t_1 after the $\pi/2$ pulse and again after the π pulse at a time Δ after the start of the first gradient pulse. The width of each gradient pulse is δ . Using the calculation method of Torrey⁵⁵ and Abragam,⁷ Stejskal and Tanner derived the expression for echo attenuation for their two-pulse PFG:

$$F(t = 2\tau) = \exp\left\{-(t/T_2) - \gamma^2 D [\delta^2 (\Delta - \frac{1}{3}\delta) G^2 + \frac{2}{3}\tau^3 G_0^2 - \delta(t_1^2 + t_2^2 + \delta(t_1 + t_2) + \frac{2}{3}\delta^2 - 2\tau^2) \mathbf{G} \cdot \mathbf{G}_0]\right\} \quad (24)$$

Figure 9 Timing of rf and magnetic field gradient pulses in the PFG spin echo experiment. G is the applied gradient, G_0 is the background gradient, and the spin echo (not shown) occurs at $t = 2\tau$

where $t_2 = 2\tau - (t_1 + \delta + \Delta)$. Other parameters are defined in Figure 9. The G_0^2 term is the usual one for a constant gradient. The $\mathbf{G} \cdot \mathbf{G}_0$ (cross) term arises in the Stejskal and Tanner derivation of $F(t = 2\tau)$. To ignore the G_0 terms, it is necessary that $\delta G \gg \tau G_0$. Under these conditions the cross term is larger than the G_0^2 term, and if G_0 were essentially uniform across the sample, the cross term would make a plot of $\ln F(t = 2\tau)$ versus G^2 nonlinear.

There are stringent requirements for generating the pulsed currents that create the field gradients. The coils and sample must be firmly supported in order to minimize mechanical vibration caused by the large magnetic forces that act on the gradient coils. Since the first pulse defocuses the spins and the second refocuses them, their areas, $G\delta$ must match each other to high precision. For example, at a maximum gradient strength of 0.1 T m^{-1} with a 0.2 cm diameter sample and pulse widths of the order of 10 ms , one pulse gives ^1H spins an angular displacement of more than 10^4 rad. Therefore the matching precision must be better than 10 ppm for reproducible echo amplitudes. Callaghan⁵⁶ recently proposed a sequence to improve this pulse matching.

3.3.2 Background Gradients

The G_0 associated with a very homogeneous applied field B_0 is usually negligible. But in samples that are heterogenous on a small length scale, background gradients can be large. The apparently anomalous rapid transverse decay of the ^7Li spin envelope of liquid lithium was attributed by Zamir et al.⁵⁷ to diffusion in the distribution of background gradients in closely, but randomly, packed spherical lithium particles in oil. Similar effects were observed⁵⁸ in the NMR of ^1H in small granules of $\text{NbH}_{0.7}$. The importance of particle size is evident in their estimate of the typical $G_0 \approx 3\chi_0 B_0/R$, where χ_0 is the magnetic susceptibility of lithium and R is a typical particle radius. In lithium, for $B_0 = 1.0 \text{ T}$, G_0 exceeds 0.1 T m^{-1} (10 G cm^{-1}) for particle radii of about 10^{-5} m . If the distribution of values of G_0 is symmetric about zero, the effect of the cross term would vanish for $\delta G \gg \tau G_0$. The effect of the cross term in second order is to reduce the *apparent* value of D deduced from the data.⁵⁹ G_0 can be reduced by reducing B_0 or by using larger particles. For metals, small particles are needed for penetration of the rf field and a good coil filling factor. This and a loss of signal-to-noise ratio at lower fields

work against reduction of G_0 . Pulse techniques for reducing or eliminating the cross term are listed in Section 3.3.4

3.3.3 Restricted Diffusion

In the derivations of the echo attenuation, it is assumed that the sample has infinite extent. For the PFG experiment, this means that $(2D\Delta)^{1/2} \ll d$, where d is the spacing between sample boundaries in the direction of the gradient. If this condition is not well met, the apparent value of D will be less than the true value. For some high diffusivity solids such as metal hydrides and fast ion conductors, diffusion might be restricted in the time of PFG measurements. A practical expression for echo attenuation in the PFG experiment on samples with spherical boundaries has been calculated by Murday and Cotts⁵⁹ who adapted the ‘constant gradient’ model of Newman.⁶⁰ Tanner and Stejskal⁶¹ have calculated expressions for PFG echo attenuation for planar, cylindrical and spherical boundaries in the approximation that $\delta \ll \Delta$. Kärger, Pfeifer, and Heink⁶² have reviewed the principles and applications of diffusion measurements by NMR.

3.3.4 Other Pulse Sequences

In the PFG spin echo experiment, the minimum measurable diffusion coefficient is inversely proportional to the diffusion time Δ , and Δ is limited by T_2 of the spin system. In systems where $T_1 \gg T_2$, the stimulated spin echo experiment can provide a greater diffusion time, since the time between the defocusing and refocusing intervals is limited by T_1 . Tanner⁶³ proposed the stimulated echo sequence shown in Figure 10. In this sequence δ is still limited by T_2 , but the diffusion time is limited by T_1 . The cost of gaining an increase in Δ is an intrinsic reduction in the echo amplitude by a factor of $\frac{1}{2}$ created by the ‘storage’ of the spin magnetization along the z axis between second and third rf pulses. Tanner calculated the echo attenuation for the stimulated spin echo PFG experiment to be

$$F[t = (\tau_1 + \tau_2)] = -\gamma^2 D \left\{ \delta^2 \left(\Delta - \frac{1}{3}\delta \right) G^2 + \tau_1^2 \left(\tau_2 - \frac{1}{3}\tau_1 \right) G_0^2 - \delta [\tau_1^2 + \tau_2^2 + \delta(t_1 + t_2) + \frac{2}{3}\delta^2 - 2\tau_1\tau_2] \mathbf{G} \cdot \mathbf{G}_0 \right\} \quad (25)$$

Figure 10 Timing of rf and magnetic field gradient pulses for the PFG stimulated echo experiment. The applied gradient is G , and G_0 is the background gradient. The stimulated echo is shown peaking at $t = (\tau_1 + \tau_2)$. (Reproduced by permission of The American Institute of Physics from J. E. Tanner, *J. Chem. Phys.*, 1970, **52**, 2523)

where $t_2 = \tau' - (t_1 + \delta + \Delta)$. The times in equation (21) are defined in Figure 10. The diffusion time Δ is approximately $(\tau_2 - \tau_1)$.

A number of techniques have been developed to reduce or eliminate effects of the cross term in equations (20 and 21). Karlick and Lowe⁶⁴ invented a very effective pulse sequence that *eliminates* the cross term and substantially reduces the effect of the G_0^2 term relative to the G^2 term. It requires bipolar (or alternating) gradient pulses, and utilizes the Carr–Purcell⁶ spin echo train with one gradient pulse inserted between each pair of π pulses; that is, δ is limited by 2τ instead of τ . In this scheme, the minimum usable Carr–Purcell sequence has five π pulses, and it can be extended by units of four such pulses at a time. The technical requirement of bipolar current pulses is not insignificant.

The Karlick–Lowe concept has been extended to the stimulated echo experiment,⁶⁵ with three different sequences that eliminate the cross term in the expression for echo attenuation. All these sequences use bipolar gradient pulses. One simple unipolar sequence reduces the ratio of the cross term to the G^2 term by a factor of about τ/Δ , which is less than the factor of about unity in the Tanner stimulated echo PFG experiment. In summary, the systematic errors due to background gradients can be nearly eliminated in diffusion coefficient measurements (see *Diffusion Measurements by Magnetic Field Gradient Methods*).

4 APPLICATIONS OF NMR TO DIFFUSION IN SOLIDS

4.1 Solids with Low Vacancy Concentrations

4.1.1 Lithium

Solid lithium is a good example of a simple elemental low-vacancy solid which has been investigated by relaxation rate and PFG diffusion coefficient measurements. Lithium has the b.c.c. structure from about 77 K to its melting point at 454 K. The ^7Li relaxation times have been measured over this full temperature range, covering both the strong and weak collision regimes, and they have been analyzed over eight decades of lithium jump rates from about 3 s^{-1} to $3 \times 10^8\text{ s}^{-1}$ between 200 K and the melting point.⁶⁶ (Messer and Noack⁶⁶ give references to earlier works.) Direct PFG measurements of D in the solid have been made by Mali et al.⁶⁷ at temperatures above about 350 K where $D > 10^{-13}\text{ m}^2\text{ s}^{-1}$ for both ^6Li and ^7Li in nearly isotopically pure and mixed samples. There is consistency between these D measurements and lithium atomic jump rates analyzed from relaxation data using lattice specific encounter models. These results demonstrate the importance of assembling relaxation data over a wide range of NMR frequencies as well as temperature. An exemplary data set⁶⁸ for R_1 and $R_{1\rho}$ is shown in Figure 11.

Messer and Noack⁶⁶ combined the R_1 data of Figure 11 with $R_{1\rho}$ data⁶⁹ at one ω_1 and strong collision data.⁵³ These data were analyzed with the monovacancy encounter theory of Wolf²⁸ and the encounter model with divacancies,⁷⁰ for the self-diffusion coefficient with the following expected temperature dependence:

$$D_{\text{SD}} = D_{10} \exp(-E_1/RT)[1 + D_{12} \exp(-E_{12}/RT)] \quad (26)$$

Figure 11 Temperature dependences of T_1 and $T_{1\rho}$ of ^7Li in solid lithium. The T_1 curves are labeled with the NMR frequency, and the $T_{1\rho}$ curves list the rotating frame magnetic field in oersteds (1 Oe $\equiv 1 \times 10^{-4}$ T). The upper limits on values of relaxation times is set by the conduction electron relaxation mechanism. (From Messer⁶⁸)

D_{SD} simply expresses the mean jump rate τ_d^{-1} of lithium atoms in that, by definition,⁶⁶ $D_{\text{SD}} = l^2/(6\tau_d)$, where l is the nearest neighbor distance in the b.c.c. lattice. Results of the analysis are plotted in Figure 12. The evident deviation from the Arrhenius relationship in equation (22) at high temperatures is attributed to divacancies and is offered as the explanation of the form of the curve in Figure 12. They obtained $E_1 = 50.2\text{ kJ mol}^{-1}$, $E_{12} = 16.7\text{ kJ mol}^{-1}$, $D_1 = 3.8 \times 10^{-6}\text{ m}^2\text{ s}^{-1}$, and $D_{12} = 2.5 \times 10^{-2}\text{ m}^2\text{ s}^{-1}$. Using the set of data in Figure 11 with a modified formula for the strong collision regime, Messer⁶⁸ obtained values of D_{SD} a factor of about 1.5 greater than those he reported previously.⁶⁶ A similar analysis has been done in solid sodium,⁷¹ but without the availability of R_1 data which were masked because of the stronger conduction relaxation rate in sodium.

PFG measurements⁶⁷ of D are given in Figure 13 for three lithium samples having different isotopic composition. These data occur in the high temperature range where the divacancy term in equation (22) appears to be in evidence. The PFG measurements⁶⁷ of D have been compared with the two sets of D_{SD} from Messer and Noack⁶⁶ and Messer.⁶⁸ Theoretically, for the b.c.c. lattice with monovacancies only, $(D/D_{\text{SD}}) = f_t = 0.727$. Mali et al.⁶⁷ found values of this ratio to be between about 0.33 and 0.60, depending on temperature for the data analysis used by Messer and Noack.⁶⁶

4.1.2 Fluorides

As noted in Section 2.2.3, the work^{32–34} on pure and doped BaF_2 represents a very successful application of NMR to a low-vacancy system. The comparison made by Figueroa et al.³⁴ between values of D calculated by analysis of relaxation rate data and values of D deduced from electrical conductivity is shown in Figure 14 (from the review by Chadwick).⁷² Experimentalists who have ever taken NMR data from samples at temperatures within a few hundred degrees of these high temperatures (up to about 1200 K) will especially appreciate Figure 14. The same research group settled many questions regarding the interpretation of relaxation rates in PbF_2 at high

Figure 12 Temperature dependence of the self-diffusion coefficient D_{SD} based on ^7Li relaxation times measured in solid lithium. temperatures by making direct PFG diffusion measurements of fluoride ions and showing their agreement with D deduced from conductivity measurements.⁷³

4.1.3 Plastic Crystals

Some molecular crystals with approximately spherical molecules, e.g. adamantane, have a plastic phase just below the melting point in which the molecules are in a state of rapid reorientation combined with translational diffusion. Many of these solids have low melting points, and so the transition to the plastic phase limits the temperature range for their study. The rapid reorientation effectively averages out the intramolecular dipole interaction and provides the fluctuating fields needed for spin relaxation. The understanding of the rotational motion has relied on analysis of NMR relaxation rate measurements. Analyses of the several spin relaxation rates have identified translational jumping rates of the rotators in the plastic phase, but the jump rates are usually so low near the melting point that PFG measurements of D have not been practical. Typically, the plastic crystal has f.c.c. or b.c.c. structure, considering the equilibrium sites of the rotators, and

Figure 13 Temperature dependence of ^7Li diffusion coefficients in solid lithium measured with the PFG spin echo technique. (○, ●) Natural lithium (92.6% ^7Li , 7.4% ^6Li); (▲) sample with 99.97% ^7Li ; (×) sample with 95.5% ^6Li , 4.5% ^7Li . (○) Magnetic field $B_0 = 2.11$ T; for all other symbols, $B_0 = 5.17$ T. Heithjans, *J. Phys. F: Met. Phys.*, 1988, **18**, 403)

monovacancy diffusion obtains in these systems. Observations of R_2 and the peak(s) in $R_{1\rho}$ at one or more values of ω_1 have been most useful in exposing diffusion because τ_d is usually too long to allow observation of the peak in R_1 at the selected NMR operating frequencies. Figure 15 shows relaxation time data for the ordered and the b.c.c. plastic phase

Figure 14 Temperature dependence of ^{19}F diffusion coefficients in BaF_2 single crystals: (a) pure; (b) doped with 0.04 mol% KF ; (c) doped with 0.05 mol% LaF_3 . of hexamethylethane (HME).⁷⁴ The reorientational motion in the low-temperature phase produces the minimum in T_1 and in $T_{1\rho}$, and the effects of the translational motion in the plastic phase is similarly evident. In the plastic phase, second moment measurements indicated isotropic molecular reorientation.

From the encounter model for monovacancies,^{25,28} estimates of D deduced from NMR relaxation times for three compounds have been compared with D obtained from radio-tracer results, with acceptable agreement.⁷⁵ In HME, $D \approx 1 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$ at the melting point (374 K). Boden has prepared a review of NMR in plastic crystals.⁷⁶

4.2 High-Vacancy Solids

4.2.1 Metal Hydrides

Nearly half of the transition metals, the rare earth metals, and many intermetallic compounds and alloys can absorb large amounts of hydrogen, which for some systems can exceed three hydrogen atoms for each metal (M) atom. Usually the hydrogen resides as atoms in one set of interstitial sites of the metal host lattice, though not necessarily the lattice of the pure, unhydrided metal. Norberg⁷⁷ explored the application of NMR early to metal hydrides by conducting pulsed and continuous wave experiments on PdH_x and identifying motional narrowing, susceptibility shifts, and testing for the conduction electron relaxation mechanism.

High diffusivities of the hydrogen atoms (i.e. those exceeding $10^{-9} \text{ m}^2 \text{ s}^{-1}$) can occur in these metal–hydrogen

(M–H) systems. Wide ranges of hydrogen solubility exist wherein hydrogen atoms reside nearly randomly (subject to site-blocking effects) on one set of sites. Vacancy concentrations can be large. Fractional concentrations exceeding 0.2 are not unusual, but ‘monovacancy’ levels are rare. This means that there are opportunities in M–H systems to use mean field,²⁶ multiple scattering,¹⁸ or Monte Carlo³⁹ models in relaxation rate analyses. Because of its low atomic number, hydrogen has a weak conduction electron relaxation mechanism⁷⁸ to compete with relaxation due to diffusion. T_1 and T_2 are sufficiently long to allow use of the PFG methods for measuring D .

Most M–H systems are good metals. As noted earlier, systematic errors in PFG measurements are reduced if metal particles are made as large as possible. This consideration favors lower laboratory frame NMR frequencies, so that 7 MHz was selected⁴⁰ for the determination of the step length of hydrogen in the subhydrides of TiH_x . In the first PFG measurement⁷⁹ of D for hydrogen in the metal hydride, $\text{NbH}_{0.6}$, a cylindrical single crystal was used partly to avoid the concerns over small particles. This experiment⁷⁹ also combined R_1 and D measurements to determine the step length. In a series of measurements on b.c.c. hydrides, summarized by Sevilla and Cotts,⁸⁰ two special PFG sequences^{64,81} were used to eliminate the $\mathbf{G} \cdot \mathbf{G}_0$ cross term. Hydrogen is found to be more mobile in the b.c.c. host metals than in those with more closely packed metal atoms.⁸⁰

The combining of measurements of D and R_1 to learn about step lengths has been done impressively by a collaboration between the Stuttgart Max Planck Institute and Iowa State University groups. Majer et al.^{42,82} have measured D for ^1H using the PFG stimulated echo⁶³ for five concentrations of hydrogen in the subhydride ZrH_x at temperatures from 600 to 950 K using applied gradients up to 25 T m^{-1} . Their results are shown in Figure 16. Using lattice specific R_1 theories,^{14,18,43} combined with R_1 measurements by Han et al.⁸³ on the same samples, it was demonstrated that hydrogen atoms jump between nearest neighbor tetrahedral interstitial sites.

Figure 16 Temperature dependences of diffusion coefficient of hydrogen in five samples of ZrH_x measured by the ^1H PFG stimulated echo. (—) Fits to the data with the Arrhenius equation. (Reproduced by permission of IOP Publishing, Ltd from G. Majer, W. Renz, and R. G. Barnes, *J. Phys. Condens. Matter*, 1994, **6**, 2935)

Non-Arrhenius plots at high temperatures for high concentration samples have been attributed to having a small fraction of hydrogen atoms located on a second, but as yet unidentified, site. References cited by Han et al.⁸³ offer a good introduction to the literature on applications of NMR in metal hydrides (see *Hydrogen–Metal Systems*).

4.2.2 Fast Ion Conductors

In the more than 20 years that there has been a high level of interest in understanding ionic conductivity in solids, NMR has been an important tool for the study of structure and ionic motion in what are regularly known as ‘solid electrolytes’ or ‘superionic conductors’. The work on the fluorides which has already been mentioned^{32–34,74,75} is representative of the application of NMR in this field. The search for high ionic conductivity has identified a wide variety of solids that meet the necessary criterion. These include crystals, glasses and polymer electrolytes. The recent report by Brinkmann⁸⁴ provides an informative and comprehensive review of NMR in this field.

Interesting examples of combining R_1 measurements with the PFG technique for D are found in the work by the University of Zürich group on ^{109}Ag ($I = \frac{1}{2}$) in fast ion conductors. Because nuclear moments of both silver isotopes are less than one-twentieth of that of ^1H , it is necessary to have access to high magnetic fields to get the NMR frequency into a workable range (above 10 MHz). However, even in this frequency range signals will be low because of the low magnetogyric ratio of ^{109}Ag . Compared to working with large γ spins such as those of ^1H , ^7Li , ^{19}F , or ^{23}Na , doing the PFG experiment on silver at first appears daunting because of the γ dependence of the important exponent in the echo attenuation expression in equation (20): $[\gamma^2 D \delta^2 (\Delta - \frac{1}{3} \delta) G^2]$. This term should equal or exceed unity in order effectively to attenuate the echo. However, because γ of ^{109}Ag is small, its relaxation rates are also reduced, so the difference can be made up by increasing the times δ and Δ in the sequence. Nevertheless, the long relaxation times and the lower NMR signal amplitudes mean longer signal accumulation times for an acceptable signal-to-noise ratio and good data.

Looser et al.⁸⁵ used the PFG spin echo technique to measure D in the two isostructural crystals RbAg_4I_5 and KAg_4I_5 from 150 to 300 K covering the α and β phases of these crystals. They found little difference in D between these crystals except in the α – β phase transition temperatures, which are visible in Figure 17. From comparison between D measured by the PFG and D_σ deduced from conductivity data, they concluded that there was increased correlation of the silver motion in the β phase.

In their work on β - Ag_3SBr , Huber et al.⁸⁶ brought together experimental data on the temperature, pressure, and NMR frequency dependence of the silver R_1 and PFG D measurements. Having the diffusion data allowed them to identify a model for silver motion that includes local hopping between the four silver sites within one face of the cubic unit cell and diffusional jumps between neighboring faces.

5 FURTHER READING

Review papers provide special perspectives on their selected applications of NMR and references to other works of interest.

1 INTRODUCTION

Diffusion measurements by field gradient methods in this article refer to the measurement of translational diffusion. Rotational diffusion and spin diffusion by means of mutual spin flips are treated elsewhere. Measurements of translational diffusion are important in the determination of sizes and shapes of molecules and molecular aggregates, and NMR in the presence of magnetic field gradients is a uniquely powerful method for making such measurements. The NMR method also provides a means for correlating diffusion coefficients with chemical shifts, characterizing the microgeometry of porous materials, investigating anisotropy of organized phases, and determining degrees of solubilization, to list only a few applications. In this article we present the principles of NMR diffusion measurements and discuss some useful techniques. This represents only a sampling of an extensive field, and we rely on recent review articles to fill in some of the gaps. Also, recent advances that offer new insights and expand the range of applications are emphasized at the expense of some important older contributions. Although some applications appear as examples, a review of applications is not intended. Appropriate textbooks and reviews are cited in the various sections, and Section 12 is devoted to sources for background material and additional reading.

1.1 Fick's Laws

According to Fick's first law of diffusion, the particle flux $\mathbf{J}$ at position $\mathbf{r}$ is proportional to the gradient of the concentration. Thus,

$$\mathbf{J}(\mathbf{r}, t) = -D\nabla c(\mathbf{r}, t) \quad (1)$$

where D is the diffusion coefficient and $c(\mathbf{r}, t)$ is the concentration in number of particles per unit volume. The conservation of mass is assured by the equation of continuity,

$$\frac{\partial c(\mathbf{r}, t)}{\partial t} = -\nabla \cdot \mathbf{J}(\mathbf{r}, t) \quad (2)$$

and this equation can be combined with equation (1) to obtain Fick's second law of diffusion:¹

$$\frac{\partial c(\mathbf{r}, t)}{\partial t} = D\nabla^2 c(\mathbf{r}, t) \quad (3)$$

It is assumed that D has at most a weak dependence on the concentration and that the concentration is low. However, equation (3) is useful over a wide range of concentrations.

In the following it is convenient to introduce the conditional probability $P(\mathbf{r}_0 | \mathbf{r}, t)$ that a particle initially at $\mathbf{r}_0$ will be at $\mathbf{r}$ at time t , and it is reasonable to assume that $P(\mathbf{r}_0 | \mathbf{r}, t)$ also obeys the diffusion equation so that:

$$\frac{\partial P(\mathbf{r}_0 | \mathbf{r}, t)}{\partial t} = D\nabla^2 P(\mathbf{r}_0 | \mathbf{r}, t) \quad (4)$$

The solution of equation (4) by standard means for unrestricted diffusion with the initial condition $P(\mathbf{r}_0 | \mathbf{r}, 0) = \delta(\mathbf{r}_0 - \mathbf{r})$ yields the expected Gaussian dependence on the displacement:

$$P(\mathbf{r}_0 | \mathbf{r}, t) = (4\pi Dt)^{-3/2} \exp[-(\mathbf{r} - \mathbf{r}_0)^2 / 4Dt] \quad (5)$$

The calculation of the average square displacement by means of equation (5) gives the Einstein–Smoluchowski equation:

$$\langle (\mathbf{r} - \mathbf{r}_0)^2 \rangle = 6Dt \quad (6)$$

Thus, molecular displacement resulting from diffusion is simply related to the diffusion coefficient.

1.2 The Stokes–Einstein Equation and Tracer Diffusion

Much of the interest in diffusion arises because of the connection between D and molecular size. For macromolecules, at least, this connection is usually made through the Stokes–Einstein equation:²

$$D = k_B T / f \quad (7)$$

where f is the friction factor. For a spherical particle with hydrodynamic radius R_h immersed in a fluid of viscosity η , Stokes's law gives $f = 6\pi\eta R_h$. Analytical expressions are also available for the friction factors of oblate and prolate ellipsoids and approximate results have been reported for complex structures made of identical subunits.³

The diffusion coefficient of interest here is the tracer diffusion coefficient, sometimes called the self-diffusion or intra-diffusion coefficient.² Nuclear spin states provide perfect labels that have almost no effect on the hydrodynamic properties of molecules. The samples under study are homogeneous and the translational motion of nuclear spins can be detected directly as described below. In a mixture with $N + 1$ components (including the solvent) there are $N + 1$ distinct tracer diffusion coefficients. This must be contrasted with the situation in which there are concentration gradients, and molecular species diffuse into each other in a process called ‘interdiffusion’. The diffusion coefficients measured in such systems are known as the ‘mutual diffusion’ or ‘interdiffusion’ coefficients. In the limit of infinite dilution, tracer and mutual diffusion coefficients are equal, but at higher concentrations they may be quite different. Also, mutual diffusion in mixtures invariably involves coupled flows, and in a volume fixed frame a system with $N + 1$ components has $N(N + 1)/2$ independent Onsager diffusion coefficients.

Dynamic light scattering (DLS), a method that depends on concentration fluctuations, is often used to measure mutual diffusion coefficients.^{4,5} DLS is a standard method, even though the diffusion coefficients obtained are not necessarily equal to the mutual diffusion coefficients that are measured with macroscopic concentration gradients.⁶ At low concentrations NMR and DLS give similar diffusion coefficients for macromolecules in solution, but the dependence on concentration is usually much stronger for tracer diffusion coefficients than for mutual diffusion coefficients. In contrast to equation (7), the mutual diffusion coefficient D_m for a macromolecule can be expressed as

$$D_m = \frac{k_B T}{f} \left(1 + \frac{\partial \ln \gamma'}{\partial \ln c} \right) (1 - \phi') \quad (8)$$

where γ' is the activity coefficient and ϕ' is the volume fraction of solute.^{7,8} Primes have been used here since the same symbols are used elsewhere for different quantities. The last two factors on the right-hand side of equation (8) largely account for the difference between mutual and tracer diffusion coefficients, but in principle the friction factors for mutual and tracer diffusion are not equal.⁹

2 EFFECTS OF TRANSLATIONAL MOTION IN NMR

The ability of NMR to detect translational motion and to image spin density depends on two essential facts: (1) a nucleus at position $\mathbf{r}$ precesses with the frequency

$$\omega(\mathbf{r}) = -\gamma B(\mathbf{r}) \quad (9)$$

where γ is the magnetogyric ratio and $B(\mathbf{r})$ is the magnitude of the local magnetic field (flux density), and (2) the local fields can be manipulated through the use of magnetic field gradients so that the spatial positions of nuclei can be encoded. The spin echo experiment is the basis of NMR diffusion measurements, since this experiment involves the refocusing of magnetization in inhomogeneous magnetic fields, a process that is extremely sensitive to the translational motion of spins.

2.1 Spin Echoes and Magnetization Helices

Consider the experiment illustrated in Figure 1(a) for a sample with a single resonance line. The applied magnetic field is in the z direction and a hard 90°_x rf pulse at $t = 0$ rotates magnetization from all parts of the NMR active volume into the y direction. Here x and y refer to a reference frame rotating about the field direction at the average precession frequency ω_0 for spins in the applied field B_0 . The resultant magnetization in each differential volume element is described by a vector (known as an ‘isochromat’) that precesses in the xy plane at a frequency that depends on the local field as indicated by equation (9). The interpretation is simpler if the inhomogeneity results from a constant field gradient $\mathbf{g}$ applied and controlled externally. Such a gradient is described by:

$$\mathbf{g} = \frac{\partial B_z}{\partial x} \mathbf{i} + \frac{\partial B_z}{\partial y} \mathbf{j} + \frac{\partial B_z}{\partial z} \mathbf{k} \quad (10)$$

where $\mathbf{i}$, $\mathbf{j}$, and $\mathbf{k}$ are unit vectors in the x , y , and z directions, respectively. Thus the magnitude of the total external magnetic field at $\mathbf{r}$ is given by:

$$B = B_0 + \mathbf{g} \cdot \mathbf{r} \quad (11)$$

In the following we assume that only a z gradient of magnitude $g = \mathbf{g} \cdot \mathbf{k}$ is present. In the presence of this gradient, isochromats with different frequencies are associated with different values of z , and it is instructive to represent the magnetization immediately after the 90°_x pulse as a ribbon formed by the isochromats with their tails on the centerline of the sample. Initially, the resultant magnetization in the y direction is equal to M_0 , the magnitude of the equilibrium magnetization prior to the rf pulse. The effect of the gradient is to give the isochromat at coordinate z a phase angle $\phi(z) = \gamma g z t$ with respect to the yz plane at time t . This is represented in Figure 1(b) by the magnetization helices with pitches given by $\Lambda = 2\pi/(\gamma g t)$.¹⁰ The detected signal, that is proportional to the resultant magnetization in the y direction, decays to zero with increasing time as illustrated by the FID in Figure 1(a). In the absence of diffusion the interpretation of the experiment is straightforward. The 180°_y pulse at τ rotates each isochromat about the y axis and thus changes the phase angle of the isochromat at z by the amount $-2\gamma g z \tau$. Precession then continues as before since the local magnetic field is unaffected by the rf pulse. In the period between τ and 2τ the helix unwinds so that the resultant is again directed along the y axis (in the absence of directed flow) and a spin echo signal is created. Thus, the isochromats have been refocused and the only attenuation of the echo results from the intrinsic T_2 of the sample, i.e. the echo amplitude is proportional to $M_0 \exp(-t/T_2)$.

2.2 Bloch Equations including Diffusion

As emphasized in Figure 1(b), the effect of the 90°_x pulse followed by the z gradient is to create a magnetization pattern in the sample. Diffusion smears out this pattern and leads to attenuation of the spin echo. The tightly wound helices are more easily disturbed by diffusion, and analytical equations

Figure 1 Spin echoes with a constant gradient: (a) the Hahn spin echo pulse sequence; (b) magnetization helices formed by isochromats; and (c) the effective gradients in the presence of a 180° rf pulse

can be derived to describe this effect. In the standard mathematical description of this experiment a term describing the rate of translational diffusion of magnetization is added to the Bloch equations to obtain a macroscopic theory of diffusion effects in NMR. Following the notation of Abragam¹¹ this gives,

$$\frac{\partial \mathbf{M}(\mathbf{r}, t)}{\partial t} = \gamma \mathbf{M} \times \mathbf{B}(\mathbf{r}, t) - \frac{M_x \mathbf{i}' + M_y \mathbf{j}'}{T_2} - \frac{(M_z - M_0) \mathbf{k}'}{T_1} + D \nabla^2 \mathbf{M} \quad (12)$$

A more convenient equation for the investigation of transverse magnetization is obtained from equation (12) by defining the complex magnetization $M_+ = M_x + iM_y$, setting $B_x = B_y = 0$, and denoting the magnitude of the average precession frequency in the sample by $\omega_0 = \gamma B_0$. The resulting equation is

$$\frac{\partial M_+}{\partial t} = i\omega_0 M_+ - \frac{M_+}{T_2} - i\gamma (\mathbf{g} \cdot \mathbf{r}) M_+ + D \nabla^2 M_+ \quad (13)$$

The uninteresting parts of the time dependence are then transformed away by means of the substitution

$$M_+ = \psi \exp(i\omega_0 t - t/T_2) \quad (14)$$

to yield the equation¹²

$$\frac{\partial \psi}{\partial t} = -i\gamma g z \psi + D \nabla^2 \psi \quad (15)$$

In the absence of diffusion equation (15) is easily solved for the magnetization in the rotating frame as a function of z and t . If the initial condition is a coherent state created by a 90° rf pulse, the magnetization pattern evolving under the influence of g is just the helix previously described. A gradient pulse with amplitude g and duration δ is said to have an area of $q = \gamma g \delta$, and the helix at the end of the pulse is described by $S(z) = m \exp(-iqz)$, where m is the magnetization density per unit length in the z direction. The integral of the effective gradient areas at the time of the echo must be zero so that the pitch of the helix becomes much larger than the active volume. This can be achieved either by reversing the direction of the gradient to obtain a 'gradient echo' or by applying a 180° pulse to set back the phase to achieve a spin echo. In fact, it is convenient in mathematical derivations to replace 180° rf pulses by the inversion of previous gradient pulses.¹³ The complete sequence of rf and gradient pulses can then be described by an effective $g(t)$. With this approach it has been shown that the solution of equation (15) in the presence of diffusion and a time dependent gradient can be written as

$$\ln \psi = -D \left[\int_0^t q^2(t') dt' \right] \quad (16)$$

where

$$q(t') = \int_0^{t'} \gamma g(t'') dt'' \quad (17)$$

It is important to note that gradient echoes and spin echoes have quite different properties in many experiments. The 180°

rf pulse refocuses phase dispersion resulting from background gradients, chemical shifts, susceptibility effects in heterogeneous samples, etc., while the reversed gradient pulse only refocuses phase dispersion resulting from a previously applied gradient pulse.

2.3 Diffusion Effects on Magnetization Patterns

According to Figure 1, the projection of the helix onto either the xz or the yz plane yields a simple sinusoidal grating function, e.g. $\text{Re}[S(z)] = m \cos(qz)$ for the yz plane. The effect of diffusion (in the direction of the gradient) on such a grating can be obtained immediately through the use of equation (5). First we integrate over the x and y coordinates to obtain

$$P(z_0 | z, t) = (4\pi Dt)^{-1/2} \exp[-(z - z_0)^2 / 4Dt] \quad (18)$$

Then $P(0 | z, t)$ is convoluted with $S(z)$ to obtain an expression for the time dependent gratings. The effect of diffusion is to 'smear out' the spatial gratings, and the time dependent helix is described by $S(z, t) = S(z) * P(0 | z, t)$, where '*' means convolution, and we can write

$$S(z, t) = \frac{m}{(4\pi D\Delta)^{1/2}} \int_{-\infty}^{\infty} \exp(-iqz') \exp[(z - z')^2 / 4Dt] dz' \quad (19)$$

Equation (19) can be evaluated directly or by means of the convolution theorem to obtain

$$S(z, t) = m \exp(-iqz) \exp(-Dq^2 t) \quad (20)$$

This expression includes the amplitude attenuation resulting from diffusion for a helix with a constant q value, i.e. a constant pitch. The attenuation factor can also be recognized as $F(q, t)$, the spatial Fourier transform of $P(0 | \mathbf{r}, t)$:

$$F(q, t) = \int_0^{\infty} P(0 | \mathbf{r}, t) \exp(-iq \cdot \mathbf{r}) d\mathbf{r} \quad (21)$$

The time evolution of $F(q, t)$ is described by the spatial Fourier transform of equation (4). This gives

$$\frac{\partial F(q, t)}{\partial t} = -Dq^2 F(q, t) \quad (22)$$

and we again find that $F(q, t) = F(q, 0) \exp(-Dq^2 t)$. Note that the right-hand side of equation (21) can be interpreted as an average of the phase factor over the distribution of displacements. This viewpoint is explored in Section 5.

2.4 Echo Attenuation in a Constant Gradient

When gradients are present and q is time dependent, $S(z, t)$ in equation (20) describes the evolution of the attenuation factor at a specific time, and the cumulative attenuation is obtained by multiplying together the attenuation factors for

the differential time increments. As expected, this procedure yields the diffusion factor displayed in equation (16).

As an illustration of the use of equation (16), consider the echo attenuation for the simple $90^\circ_x - \tau - 180^\circ_y - \tau$ echo experiment shown in Figure 1. In the regions 0 to τ and τ to 2τ the effective gradient amplitudes are $-g$ and g , respectively, as shown in Figure 1(c), and equation (17) gives

$$q(t) = -\int_0^t \gamma g dt', \quad 0 < t < \tau$$

$$q(t) = -\gamma g \tau + \int_\tau^t \gamma g dt', \quad \tau < t < 2\tau \quad (23)$$

$q(t)$ from equation (23) is then substituted into equation (16) to obtain

$$\ln \psi(2\tau) = -D(\gamma g)^2 \left[\int_0^\tau (t')^2 dt' + \int_\tau^{2\tau} (t' - \tau)^2 dt' \right] \quad (24)$$

Therefore, the attenuation resulting from diffusion at the echo time 2τ is found to be

$$\ln \psi(2\tau) = \frac{1}{12} D \gamma^2 g^2 (2\tau)^3 \quad (25)$$

and the total echo amplitude $S(2\tau)$ is given by

$$S(2\tau) = M_0 \exp(-2\tau/T_2) \exp[-D\gamma^2 g^2 (2\tau)^3 / 12] \quad (26)$$

The well-known τ^3 dependence of the exponent in the diffusion factor is the reason why the simple spin echo experiments are usually not satisfactory for the measurement of T_2 .^{14,15}

3 PULSED FIELD GRADIENT NMR

The introduction of pulsed field gradients (PFGs) in place of steady gradients for diffusion measurements greatly improves the spin echo diffusion experiment and opens a wide range of applications.¹² The basic Stejskal-Tanner experiment, illustrated in Figure 2, has two major advantages over constant gradient methods. First, by confining the gradients to relatively narrow time intervals, this experiment permits gradient areas to be varied without changing the echo time, so that the attenuation resulting from relaxation can be held constant. Second, the echo can be recorded in a homogeneous magnetic field. Spectral information is, therefore, retained and frequency resolved diffusion measurements are possible. These advantages are widely acknowledged, and almost all modern NMR diffusion measurements are made with some form of pulsed gradient experiment. However, a disadvantage of pulsed experiments should be noted. The switched gradient experiments require current pulses that inevitably produce heat, mechanical forces, and eddy currents.

Figure 2 The Stejskal-Tanner pulsed field gradient spin echo diffusion experiment

3.1 The Spin Echo SE Diffusion Experiment

The echo attenuation resulting from diffusion with the sequence shown in Figure 2 can be obtained by direct application of equation (16). The total echo amplitude is given by¹²

$$S(2\tau) = M_0 \exp(-2\tau/T_2) \exp[-Dq^2(\Delta - \delta/3)] \quad (27)$$

where $q = \gamma g \delta$ and the effect of transverse relaxation has been included. The attenuation factor $\psi(2\tau)$ for diffusion alone is easily isolated by taking the ratio of the echo amplitude with applied gradient switched on, $S(2\tau)$, to the amplitude with gradient switched off, $S_0(2\tau)$. Thus $\psi(2\tau) = S(2\tau)/S_0(2\tau)$. However, transverse relaxation diminishes the signal-to-noise ratio and may present a serious problem for slowly tumbling macromolecules and molecular aggregates where T_2 values tend to be short. Transverse relaxation and J modulation effects present special problems for coupled spin systems.^{16,17} T_2 is often much shorter for coupled spins than expected from the rotational correlation times alone, and spin coupling in homonuclear spin systems can prevent complete refocusing of the spin echo. The latter effect arises because hard rf pulses exchange the spin states of nuclei that are coupled to the nuclei under observation. Precession frequencies change, and refocusing depends on the magnitude of the spin coupling constant J . For a coupled pair of spin- $\frac{1}{2}$ nuclei this leads to echo maxima when $\tau = n/J$ and negative echoes when $\tau = n/(2J)$, where n is an integer and J is in hertz.

Equation (27) is appropriate for the analysis of experimental data when the magnetic field B_0 is homogeneous and the gradient pulses are well matched. It may be possible to approximate the effect of an inhomogeneous magnetic field by a constant background gradient g_0 . The effective gradient is then $g + g_0$ and a complete analysis gives the diffusion factor:¹²

$$\begin{aligned} \psi(t) = \exp\{ & -D\gamma^2[g^2\delta^2(\Delta - \delta/3) + 2g_0^2\tau^3/3 \\ & -g \cdot g_0\delta(t_1^2 + t_2^2 + \delta(t_1 + t_2) \\ & + 2\delta^2/3 - 2\tau^2)] \} \end{aligned} \quad (28)$$

Gradient pulse mismatch changes the position and intensity of the echo. Some investigators have resorted to adjusting the

width of the second gradient pulse to reposition the echo, but this is not a practical solution in experiments where the gradient areas are automatically ramped through a series of values and the signal is recorded starting from the center of the echo. A detailed analysis shows that sensitivity to the gradient pulse mismatch is decreased by the application of a constant gradient parallel to the gradient pulses.¹⁸

3.2 The Stimulated Echo Diffusion Experiment

A sequence containing three 90° rf pulses was among the first echo forming sequences studied by Erwin Hahn in his pioneering work on time dependent NMR.¹⁴ He found that five echoes are formed in a steady gradient experiment. As shown in Figure 3(a) they are the primary echo (PE) at $2\tau_1$, the stimulated echo (STE) at $\tau_1 + \tau_2$, and three secondary echoes that are usually not of interest. The effect of diffusion on the STE has been investigated for a steady gradient¹⁹ and for gradient pulses.²⁰ Both versions of the experiment are of current interest (Section 9), but this section focuses on pulsed gradients.

An intuitive understanding of the formation of the stimulated echo can be gained from the graphical representation of the isochromats shown in Figure 3(b). Here the superscripts $(-)$ and $(+)$ indicate 'immediately before' and 'immediately after' the rf pulse at the indicated time. The magnetization ribbon at 0^+ , characterized by $q = 0$, is wound up by the action of the first gradient pulse so that at τ_1^- the pitch of the resulting helix is $\Lambda = 2\pi/q$. In the presence of the gradient pulse and a very weak background gradient, $q \approx \gamma g \delta$. The new feature here is the rf pulse at time τ_1 that rotates each isochromat through 90° about the $-x$ axis so that its y component is stored in the z direction. The resulting pattern of z magnetization is responsible for the STE. At τ_2 the third 90° rf pulse rotates the z magnetization back into the yx plane. If this pulse is directed along the x axis, the isochromats all become collinear with the y axis so that the magnetization lies in the yz plane as represented by the $\cos(qz)$ function shown in Figure 3(b). The refocusing effect necessary to form the STE results from twisting action of the second gradient on this pattern. At the time of the STE the y components of the isochromats are all positive and their resultant reaches a maximum along the y direction, even though they do not all lie in the yz plane. In fact, the projection of the tips of the isochromats onto the xy plane gives a circle tangent to the xz plane. Note that the STE results from a pattern of magnetization density in the z direction, regardless of the source of the pattern. A specially prepared sample with alternating layers having different spin densities can give an STE in an experiment with a single rf pulse.

The magnetization components remaining in the x and y directions after the second rf pulse are responsible for the primary echo and secondary echoes. These components result from the x and z components of the magnetization at τ_1^- . In the pulsed gradient experiment the PE and the secondary echoes do not refocus.

The primary advantage of the STE sequence is that the transverse evolution time for magnetization can be reduced. This is especially important when T_2 is small but, as mentioned above, can also be used to minimize the effects of J modulation. In the absence of a significant background

Figure 3 The pulsed field gradient stimulated echo (STE) diffusion experiment: (a) the pulse sequence and echoes; (b) evolution of the isochromats

gradient, i.e. when $g_0 \approx 0$, the total amplitude of the STE is given by

$$S(T + 2\tau_1) = (M_0/2) \exp(-2\tau_1/T_2 - T/T_1) \times \exp[-Dq^2(\Delta - \delta/3)] \quad (29)$$

Equation (29) also shows the major disadvantage of STE experiments, namely the amplitude of the echo is reduced by a factor of 2 relative to a spin echo (SE) if T_1 and T_2 are equal. The reason for this loss is obvious from Figure 3(b). The second rf pulse only stores the y components, and the second gradient only partially refocuses the magnetization for the STE. This loss may be recovered many times over depending on the ratio of T_2 to T_1 and the amount of attenuation. For example, when $T_2/T_1 = 0.5$ and $T/T_1 = 0.1$ the STE signal is 23% larger than an SE with the same echo time (TE), and when $T/T_1 = 0.5$ the STE is 45 times as large as the SE. It is also advantageous to keep $\tau \ll 1/J$ for spin coupled systems, in order to minimize the modulation of intensities and to make sure that all signals are positive. In general, the advantages of the STE experiment outweigh the loss of signal resulting from the factor of 0.5, and STE is becoming the standard method for diffusion measurements.

3.3 Special Sequences for Heterogeneous Samples

In some cases background gradients cannot be ignored. When the background gradients are uniform, corrections

can be applied to the attenuation factor as shown in equation (28) for the spin echo experiment. However, in heterogeneous samples where the background gradients g_0 have random magnitudes and directions and may be comparable in magnitude to the applied gradients, simple corrections are not possible. Fortunately, pulse sequences can be designed to minimize the corrupting effects of the background gradients. A useful principle is that a 180° rf pulse refocuses isochromats dispersed by a time independent gradient, but that refocusing of the effects of an applied gradient g_A can be avoided either by changing the polarity of the gradient or by applying the gradient pulse on one side of the 180° rf pulse. A number of sequences have been proposed to minimize the effect of the cross term $g_0 \cdot g_A$. Here two schemes are used as illustrations, one for SE and one for STE experiments.

The Karlicek-Lowe (KL) alternating PFG sequence is shown in Figure 4.²¹ Background gradients are effectively reversed by the second 180° rf pulse, but the effective applied gradient g_A is unchanged. The third 180° pulse begins the refocusing period, since the applied gradient is not reversed this time. Note that the intervals δ_1 and δ_2 have been introduced in the pulse sequence so that the rf pulses and the gradient pulses will not overlap. The general version of this sequence has n 180° pulses and the echo occurs at $2n\tau$. The cross term $g_0 \cdot g_A$ is avoided by requiring that the number of positive g_A intervals equal the number of negative g_A intervals, thus restricting n to the values (5, 9, ..., $4m +$

Figure 4 The Karlicek-Lowe alternating pulsed field gradient experiment for minimizing the effects of background gradients²¹

1; $m = 1, 2, 3, \dots$). The effect of the complete sequence on the echo amplitude can be calculated by means of equation (16), with the simplifying assumption that 180° pulses can be replaced with gradient reversals. The solution for the general sequence is:

$$\ln[\psi(2n\tau)] = \frac{-2\gamma^2 D}{3} \left\{ n g_0^2 \tau^3 + (n-1)^3 g_A^2 \left[\tau - \frac{(\delta_1 + \delta_2)}{2} \right]^2 \left[\tau + \frac{(\delta_1 + \delta_2)}{(n-1)^2} \right] \right\} \quad (30)$$

This sequence has been demonstrated with heterogeneous samples having g_0 values of nearly 3 kG cm^{-1} . It has also been used in imaging applications to determine the spatial distribution of diffusion coefficients.²¹

The KL sequence is effective, but is at a disadvantage for samples having T_2 much smaller than T_1 . In order to deal with short transverse relaxation times Cotts et al.²² have proposed a number of sequences based on the STE diffusion experiment. The standard STE pulsed gradient diffusion sequence in the presence of a background gradient g_0 is shown in Figure 5(a) and the attenuation factor obtained by Tanner is given by^{20,22}

$$\begin{aligned} \ln[\psi(\Delta + 2\tau)] = & -\gamma^2 D \left\{ \delta^2 \left(\Delta + \tau - \frac{\delta}{3} \right) g_A^2 \right. \\ & + \delta \left[2\tau\Delta + 2\tau^2 - \frac{2\delta^2}{3} \right. \\ & \left. \left. - \delta(\delta_1 + \delta_2) - (\delta_1^2 + \delta_2^2) \right] \right. \\ & \left. \times g_A \cdot g_0 + \tau^2 \left(\Delta + \frac{2\tau}{3} \right) g_0^2 \right\} \quad (31) \end{aligned}$$

A sequence that eliminates the cross term $g_0 \cdot g_A$ when $\delta_1 = \delta_2$ and reduces the effect of g_0^2 is shown in Figure 5(b). The attenuation factor calculated for this 13 interval sequence is

$$\begin{aligned} \ln[\psi(\Delta + 4\tau)] = & -\gamma^2 D \left[\delta^2 \left(4\Delta + 6\tau - \frac{2\delta}{3} \right) g_A^2 \right. \\ & \left. + 2\tau\delta(\delta_1 - \delta_2) g_A \cdot g_0 + \frac{4\tau^3 g_0^2}{3} \right] \quad (32) \end{aligned}$$

A number of more effective but also more complicated sequences have been designed. For example, a 17 interval sequence that is the STE version of the KL sequence with storage at 6τ and recovery of transverse magnetization at $\Delta + 6\tau$ has the advantages of the 13 interval sequence but gives a

Figure 5 (a) The standard stimulated echo (STE) sequences with a background gradient. (b) A 13 interval STE sequence for minimizing the effects of background gradients²²

larger coefficient for g_A^2 . An extension to n pairs of gradient pulses ($n \leq 12$) has been found to be even more effective in eliminating the effects of g_0 .²³

3.4 Modulated Gradients

Modulated gradients, in particular gradients with sinusoidal time dependence, have been suggested as alternatives to pulsed gradients.^{12,24} Modulated gradients may be easier to implement than pulsed gradients and may cause less trouble with eddy currents in metal magnet structures. These advantages have not yet attracted many users. However, modulated gradients should be of interest for another reason: they introduce flexibility into NMR studies of motion and may permit frequency-dependent diffusion coefficients to be studied that are inaccessible with conventional PFG-NMR experiments.^{25,26}

In transport theory the frequency dependent self-diffusion tensor is defined as the spectrum of the velocity correlation function:

$$D_{\alpha,\beta}(\omega) = \frac{1}{2} \int_{-\infty}^{\infty} \overline{v_{\alpha}(0)v_{\beta}(t)} \exp(i\omega t) dt \quad (33)$$

where α and β represent the Cartesian coordinates x, y, z . In order to investigate the frequency dependence of $D_{\alpha\beta}(\omega)$, Stepisnik²⁶ has developed a general theory for the echo attenuation exponent $\alpha(t)$, defined by $\psi \propto \exp[-\alpha(t)]$, in the presence of a modulated gradient. Under certain conditions $\alpha(t)$ can be expressed as

$$\alpha(t) = \frac{1}{2\pi} \gamma^2 \int_{-\infty}^{\infty} D_{zz}(\omega) S(\omega, t) d\omega \quad (34)$$

where

$$S(\omega, t) = \frac{|\mathbf{g}(\omega, t)|^2}{\omega^2}, \quad \mathbf{g}(\omega, t) = \int_0^t \mathbf{g}_{\text{eff}}(t') \exp(-i\omega t') dt' \quad (35)$$

Here $\mathbf{g}_{\text{eff}}(t)$ includes inversions to account for 180° pulses, as discussed in Section 2.2. Equation (34) shows that echo

Figure 6 Sinusoidal modulation: the gradient $g_{\text{eff}}(t)$ and its spectrum $S(\omega, t)$ ²⁵

attenuation depends on the spectral density of molecular motion and the spectrum of the gradient.

This ‘gradient spectrum’ formulation is consistent with the Stejskal–Tanner result for the conventional gradient echo experiment that depends on $D(0)$. The power of Stepisnik’s method is revealed with modulated gradients that offer the possibility of probing the frequency dependence of $D(\omega)$. For example, Figure 6 shows a sinusoidal gradient with amplitude g and its spectrum, and the application of equation (34) gives:

$$\alpha(t) = \frac{\gamma^2 g^2}{\omega_m^2} t [D_{zz}(0) + \frac{1}{2} D_{zz}(\omega_m)] \quad (36)$$

Therefore, $D(\omega)$ can be investigated by measuring $\alpha(t)$ for different modulation frequencies. It has been pointed out that this technique permits rapid motions to be investigated without reducing the evolution period.

3.5 Radiofrequency Field Gradients

The difficulties encountered in producing large pulsed gradient fields and in controlling the induced eddy currents are well known. A method that avoids these problems, albeit at some cost, is the use of rf field gradients in place of B_z gradients. This is essentially an extension of the rotary echo method to diffusion measurements.²⁷ A single turn rf coil around the x axis in the laboratory frame provides a B_1 field gradient, g_1 perpendicular to the B_0 field. The result is phase encoding of x positions, so that a helix of magnetization lies along the x axis. One implementation of this method (Figure 7) uses two rf coils to produce homogeneous and inhomogeneous rf fields.²⁸ An inhomogeneous pulse of length δ imparts the phase angle $\gamma g_1 x \delta$ in the yz plane at x . A homogeneous (hard) 180°_y pulse reverses the sign of the phase, and the second inhomogeneous pulse unwinds the helix to refocus magnetization along the z axis. Finally, a hard 90°_x pulse rotates the magnetization into the y direction in the rotating frame so that the signal can be detected.

The effect of diffusion is to smear out the helix as in the conventional PFG-SE experiment, and the same arguments lead to the exponential attenuation factor in equation (27). However, the effect of spin relaxation is different with rf gradients. If $T_2 \gg \Delta$, the magnetization is completely recovered by the second gradient pulse in the absence of

Figure 7 Sequence for rf gradient diffusion measurements with two coils: rf gradients g_1 and hard 90° and 180° pulses are shown²⁸

diffusion. However, with $T_2 \ll \Delta$ the isochromats are parallel to the z axis at the beginning of the second inhomogeneous pulse and refocusing only recovers half of the initial magnetization as recovered in STE experiments. Net transverse magnetization can also be removed by means of an inhomogeneous B_0 field during Δ to ensure the rotary equivalent of the STE experiment. The signal at $\Delta + \delta$ is known as a ‘stimulated rotary echo’ (SRE).²⁹ There is also an echo at 2Δ that is T_2 -weighted but may be useful for diffusion measurements. It turns out that the SRE experiment can be implemented with a single rf coil and without the hard 180°_x and 90°_x rf pulses. As in the STE experiment the 180°_x pulse is not needed, and in place of the 90°_x rf pulse the second inhomogeneous pulse can be lengthened by the amount τ that corresponds to a 90° rotation for isochromats at the center of the sample.

The rf gradient experiments are successful and provide convenient gradient switching without harmful eddy currents. Unfortunately, the gradient amplitudes are limited. The largest g_1 reported to date is 15.2 G cm^{-1} , and the measurement of small diffusion coefficients requires rf pulse lengths greater than 10 ms. Still a diffusion coefficient of $3.3 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ has been measured to within 5%, and the method is promising.²⁹

3.6 Multiple Quantum Diffusion Measurements

Multiquantum (MQ) NMR experiments have the following advantages for the study of molecular diffusion: (a) precession frequencies increase linearly with the order $n = \Delta m$ of the coherence; (b) MQ spectra are simplified with respect to the single quantum spectrum; and (c) for N coupled protons the N -quantum transition is free of dipolar couplings. The possible limitations are that the spectrum must show splittings from scalar, dipolar, or quadrupolar coupling; and that, except for double quantum excitations, there is a loss of sensitivity because of the inefficient transfer of magnetization.

The first two demonstrations of MQ diffusion measurements involved solutes in liquid crystal solvents where dipolar splittings are evident.^{30,31} For example, benzene in a nematic phase diffusion permits measurements to be made with $n = 1$ to 6 by means of the pulse sequence shown in Figure 8.³¹ In this sequence MQ orders are present during the diffusion period Δ and at the MQ echo. A short gradient pulse after the echo, but during the MQ evolution, and a set of n gradient pulses after recall of single quantum coherence provide the n -quantum filter. The effective gradient is increased by a factor

Figure 8 The multi-quantum (MQ) diffusion experiment: (a) sequence for multi-quantum excitation and n -quantum filtering; (b) echo intensities for coherences with $n = 1$ to 6 for benzene in a nematic solvent³¹

of n for the n -quantum coherence and the echo attenuation factor becomes:

$$\psi(t_1) = \exp[-n^2 \gamma^2 g^2 \delta^2 D(\Delta - \delta/3)] \quad (37)$$

This effect is elegantly illustrated by the plot of echo amplitudes for benzene shown in Figure 8(b). While this experiment may be most valuable for slow moving molecules in anisotropic environments, it can also provide enhanced gradients and MQ filtering in isotropic phases when scalar coupling is present.^{32,33}

The use of zero quantum coherences in diffusion studies has been discussed in connection with the use of static gradients and the avoidance of eddy current effects.³⁴ However, high resolution is still obtained by switching off the gradient before data acquisition.

4 THE FT-PFG-NMR METHOD AND DIFFUSION ORDERED TWO-DIMENSIONAL NMR SPECTROSCOPY

The measurement of spin relaxation in complex systems by FT methods was suggested and demonstrated by Vold et al.³⁵ Their example was an inversion recovery experiment for the measurement of T_1 , but frequency resolved measurements of transverse relaxation and diffusion rates were also discussed. The simultaneous measurement of diffusion coefficients for all components in a mixture was demonstrated by James and McDonald³⁶ with a spin echo experiment similar to that illustrated in Figure 2 except that the gradient was on almost the full time between the rf pulses. The second half of the spin echo at 2τ was Fourier transformed to obtain the complete spectrum of a mixture of dimethyl sulfoxide (DMSO) and water, and the experiment was repeated for 10 values of

τ . The ratios of the peak intensities with and without the gradient pulses then gave the diffusion factor $\psi(2\tau)$ for each line. This type of experiment has been implemented on FT NMR spectrometers and applied to a variety of chemical systems.^{37–39} The work of Stilbs and coworkers in particular stimulated much interest in diffusion measurements. An early example of the FT-PFG-NMR experiment for a mixture containing chloroform, benzene, dichloroethane, 1,4-dioxane, acetone, cyclopentane, cyclohexane, and tetramethylsilane is shown in Figure 9.⁴⁰ The gradient pulse amplitude was approximately 1.2 G cm^{-1} and the different values of q were obtained by varying the duration δ as shown on the right-hand side of the figure.

FT-PFG-NMR experiments demonstrate that information about diffusion and flow can be encoded into high-resolution data sets. This is very important because it addresses the shortcoming of NMR as an analytical tool. High-resolution NMR is highly selective because it reports on details of the local environments of nuclei, i.e. short range interactions. However, NMR is not sensitive to long range interactions of nuclei ($>1 \text{ nm}$) and is only indirectly affected by the overall sizes and charges of macromolecules and molecular aggregates. Therefore, NMR is not particularly good for the analysis of complex mixtures. However, hydrodynamic properties do depend on size and charge, and FT-PFG-NMR opens the door to the utilization of this information in NMR analysis.

Diffusion ordered two-dimensional NMR (DOSY) is primarily concerned with the analysis and display of data obtained in FT-PFG-NMR experiments.⁴¹ Plots of signal intensities versus gradient pulse lengths, or areas, are somewhat analogous to FIDs. The data sets can be analyzed to determine one or possibly more diffusion coefficients, but the results are not obvious by inspection of the decay curves. Just as FIDs are Fourier transformed to obtain ‘user-friendly’ frequency spectra, diffusion dependent decays can be transformed to obtain ‘diffusion spectra’. DOSY experiments are designed to acquire automatically high-resolution NMR data sets for an exponentially spaced set of q values. The frequency spectra are obtained by Fourier transformations and the data sets at each chemical shift are inverted by approximate inverse Laplace transforms (ILTs) with respect to q^2 to generate two-dimensional diffusion spectra.

Signal stability is crucial in DOSY, and the following features have been incorporated: (i) the gradient pulses are matched within 10 ppm so that the echo positions do not vary as q is changed;⁴² (ii) currents induced by the gradient pulses are minimized through the use of actively shielded gradient coils;^{43,44} and (iii) signal distortions resulting from residual eddy currents are avoided through storage of the echo signal while the eddy currents decay. The pulse sequence chosen for this experiment is the ‘longitudinal eddy delay’ (LED) sequence shown in Figure 10.⁴⁵ This is a modified STE sequence with a fourth rf pulse to store the STE and a fifth rf pulse to recall the magnetization after the eddy current settling period. The gradient prepulses establish a steady state response so that the fourth and fifth gradient pulses will have equivalent effects.⁴⁶ Note that $\Delta = T + \tau$ and, in general, $\tau \ll T$, so that the evolution period for transverse magnetization between the first rf pulse and the STE is negligible. Also, phase cycling of the five rf pulses and a homospoil gradient pulse during T_e are used to eliminate the secondary echoes. With this

Figure 9 FT-PFG-NMR stack plot for a multicomponent mixture. The gradient pulse amplitude is constant, and the pulse duration δ increases from back to front⁴⁰

Figure 10 The LED pulse sequence. The phase cycling and homospoil pulse during T_e are not shown

system diffusion coefficients down to $10^{-10} \text{ cm}^2 \text{ s}^{-1}$ have been measured for gel stabilized samples. The lower limit for low viscosity samples is usually determined by convection currents resulting from temperature gradients.⁴⁷

In DOSY, FIDs are acquired for 20–50 exponentially spaced q values and are Fourier transformed to obtain frequency spectra. The result is a two-dimensional data set of the form

$$f(q, \nu) = \sum_{j=1}^{N_\lambda} A_j(\nu) \exp[-D_j(\Delta - \delta/3)q^2] \quad (38)$$

where $A_j(\nu)$ is the one-dimensional NMR spectrum of the j th diffusing species when $q = 0$ (taking into account transverse and longitudinal relaxation), D_j is the associated tracer diffusion coefficient, and N_λ is the number of components required for the fit. The aim is to analyze the data set for each frequency ν so that a set of amplitudes A_j and diffusion coefficients D_j is obtained. This set is then used to generate a diffusion spectrum with peak positions and amplitudes that correspond to the D_j and A_j values, respectively.

Unfortunately, the fitting of data (with noise) with an equation of the form of equation (38) is an ill-conditioned problem, and infinitely many sets of solutions may fit the data very well (see Section 10). Since it is not sufficient to fit the data, additional information must be introduced to aid in selecting the most likely solution for a real mixture. The first decision is whether the sample contains components with

well defined (discrete) diffusion coefficients or if continuous distributions, i.e. polydispersity, must be considered. In the discrete case, data inversion programs such as DISCRETE^{48,49} and SPLMOD^{50,51} are appropriate for automated analysis since they do not require initial estimates of the parameters, but they must be supplemented with prior knowledge about the nature of the acceptable solutions. For example, signal amplitudes in LED experiments (with $\tau \ll \Delta$) and decay constants (diffusion coefficients) must be nonnegative. Also, the range of physically acceptable diffusion coefficients, the diffusion coefficients accessible to the PFG-NMR experiment, and the resolving power of the SPLMOD analysis are known. This knowledge combined with data analysis experience led to the following conservative set of acceptability criteria:

1. Diffusion coefficients must be feasible and experimentally accessible.
2. Standard errors in diffusion coefficients reported by SPLMOD must be less than 30%.
3. Diffusion coefficients of components at the same chemical shift must differ by a factor of more than 2.

These rules are included in a computer algorithm so that frequently occurring artifacts can be rejected.

When a solution has been found that meets the criteria at each frequency in the NMR spectrum, the DOSY display is generated with normalized Gaussians having center positions and intensities equal to the derived diffusion coefficients and amplitudes, respectively. Thus, the DOSY display has the form

$$F(D, \nu) = \sum_{j=1}^{N_\lambda} A_j(\nu) G_j(D) \quad (39)$$

where

$$G_j = \frac{1}{\sqrt{2\pi}\sigma_j} \exp\left[-\frac{(D - D_j)^2}{2\sigma_j^2}\right] \quad (40)$$

Here σ_j is derived from the error reported by the analysis program with an allowance for systematic errors. An example

Figure 11 DOSY display processed with SPLMOD for a mixture containing toluene, benzyl alcohol, tetraethylene glycol (TEG), and SDS micelles in D_2O .⁵² The degrees of solubilization p_j are given in parentheses

of the application of DOSY to a discrete mixture is shown in Figure 11.⁵² The various solutes are solubilized by the surfactant sodium dodecyl sulfate (SDS). The solutes exchange between SDS micelles and the bulk solution so rapidly that the PFG-NMR experiment reports only the time averaged diffusion coefficient for each species. Therefore, for the j th solute the observed diffusion coefficient D_j is given by^{53,54}

$$D_j = p_j D_j^{\text{mic}} + (1 - p_j) D_j^{\text{free}} \quad (41)$$

where p_j is the degree of solubilization, and D_j^{mic} and D_j^{free} are the tracer diffusion coefficients for solubilized and free molecules, respectively. The diffusion coefficients in this example are so similar that resolution in the NMR dimension is essential for a complete analysis. High-resolution spectra were obtained in this experiment by means of a stop-and-go spinner system that permitted the sample to be stationary during the diffusion time Δ but to spin during data acquisition.⁵⁵

Continuous distributions are encountered with many systems of interest. Examples include micelles, microemulsion droplets, vesicles, and polymers. Equation (38) can be rewritten to emphasize the continuous distribution $g(\lambda)$ of diffusion coefficients contributing to the data set at a particular frequency ν . Thus

$$G(s) = \int_0^\infty g(\lambda) \exp(-\lambda s) d\lambda \quad (42)$$

where $\lambda = D$ and $s = q^2(\Delta - \delta/3)$. The factoring of the exponent in equation (38) is a matter of convenience, and in cases where $(\Delta - \delta/3)$ is constant one might choose $s = q^2$. The inversion of a data set $G(s)$ containing noise to obtain the diffusion spectrum $g(\lambda)$ is a long-standing problem in data analysis, and its ill-posed nature has been emphasized repeatedly. A large body of literature has been devoted to this problem (see Section 10). The ill-conditioned inverse Laplace transform ILT has been approached by a variety of methods including regularized least-squares (CONTIN) and maximum entropy (MEM). Thus far only CONTIN has been applied to DOSY analyses.^{41,56} In this program the linear least-squares method is augmented with prior knowledge about the nature of the solutions and the principle of parsimony. We know that the decay constants (diffusion coefficients) are nonnegative

Figure 12 DOSY display preprocessed with CONTIN for a mixture containing CTAB, PVME, and NaSal (see text)⁵⁷

and that the decay kernels are exponential. Also, as noted above, the LED experiment ensures that the signal amplitudes are positive. Parsimony implies that the simplest (smoothest) solution consistent with a priori information and the data is selected. This amounts to discriminating against solutions with high-frequency components (wiggles) by introducing a term to penalize such solutions. The weight given to the penalty is the regularization parameter α that is determined on the basis of the Fisher F -test or by input from the user. Therefore, CONTIN provides an automatic analysis that has some capability to handle multimodal distributions. The primary shortcoming is that enforced smoothness reduces the ability to resolve peaks in the diffusion spectrum and leads to overestimation of the widths of narrow peaks.

The generation of DOSY displays with CONTIN is straightforward. The $G(s)$ versus s data sets are analyzed at every frequency point where the signal-to-noise ratio exceeds a predetermined threshold value to obtain new data sets of intensities versus values of D . Stack plots or contour plots are then constructed without any additional data manipulation. An example of a CONTIN analysis is provided by the DOSY display in Figure 12 for a sample containing 25.0 mM hexadecyltrimethylammonium bromide (CTAB), 15.0 mM sodium salicylate (NaSal), and 7.40 g L⁻¹ poly(vinyl methyl ether) (PVME) at 30 °C.⁵⁷ The projections on the left-hand side show diffusion distributions for PVME, CTAB, and NaSal. The addition of PVME to the viscoelastic CTAB/NaSal sample resulted in a marked reduction in the viscosity. It is thought that the polymer reduces the length of threadlike CTAB micelles by wrapping around the micelles. Note that the polydispersity of the polymer is consistent with the width of the distribution, but that the associated CTAB shows a much narrower distribution. The width for CTAB results primarily from regularization in the analysis, since CTAB molecules exchange rapidly between aggregates associated with different PVME molecules and exchange narrowing is expected. Figure 12 also shows the smoothing effect of CONTIN on the distribution for NaSal which is monodisperse and should have a vanishingly small width. When preliminary analysis indicates that a relatively narrow unimodal distribution of diffusion coefficients is present at a particular chemical shift, the direct cumulants analysis method may be preferable to CONTIN (see Section 10).

5 THE AVERAGE PROPAGATOR AND THE SCATTERING ANALOGY

In the short gradient pulse limit ($\delta \ll \Delta$) the equations given in Section 2 for the echo amplitude can be recast in a useful and instructive form. Consider the SE experiment illustrated in Figure 2 with gradient pulses of amplitude g in the z direction. The first gradient pulse instantaneously encodes the phase shift $-\gamma\delta g z_0$ for spins at position z_0 . During the interval Δ the spins diffuse a distance Z parallel to the gradient to the position $z_0 + Z$, and finally the second gradient pulse, inverted relative to the first one or effectively inverted by a 180° rf pulse, gives the additional phase shift $\gamma\delta g(z_0 + Z)$. Thus, the net phase shift is $\gamma\delta g Z$ for spins starting at time zero. Of course, the echo arises from all of the excited spins and depends on both the initial spatial distribution of spins $\rho(z_0)$ and the conditional probability $P(z_0 | z_0 + Z, \Delta)$ that a spin at z_0 at time zero will be at $z_0 + Z$ at time Δ . The sum over all NMR active spins leads to the expression⁵⁸

$$\psi = \int \rho(z_0) P(z_0 | z_0 + Z, \Delta) \exp(iqZ) d(z_0 + Z) dz_0 \quad (43)$$

where again $q = \gamma\delta g$ and spin relaxation has been neglected.

We now define the ‘average propagator’

$$\bar{P}(Z, \Delta) = \int \rho(z_0) P(z_0 | z_0 + Z, \Delta) dz_0 \quad (44)$$

so that the echo amplitude can be written as

$$\psi(q) = \int \bar{P}(Z, \Delta) \exp(iqZ) dZ \quad (45)$$

This reveals the Fourier transform relationship between $\psi(q)$ and $\bar{P}(Z, \Delta)$ and indicates that $\bar{P}(Z, \Delta)$ can be obtained as the Fourier transform of the echo amplitude.^{59, 60} Note that for free diffusion in a homogeneous sample, the average propagator is simply the Gaussian function shown in equation (18) with Δ in place of t . Substitution of equation (18) into equation (45) gives

$$\psi(q) = 2(4\pi D \Delta)^{-1/2} \int_0^\infty \exp(-Z^2/4D\Delta) \cos(qZ) dZ \quad (46)$$

and evaluation of equation (46) shows that the echo amplitude is just $\psi(q) = \exp(-Dq^2\Delta)$, as previously derived. In general, the shape of the propagator $\bar{P}(Z, \Delta)$ is determined by average molecular displacements in the sample under study. An example is provided by the diffusion of ethane in NaCaA zeolites;⁵⁹ for further information see *Diffusion in Porous Media*.

It has been pointed out that the Fourier transformation of $\psi(q)$ provides an image of the propagator analogous to the image of spatial positions provided by magnetic resonance imaging (MRI). The q space introduced here is conjugate to the dynamic displacement space $\mathbf{R}$ or Z .

Equation (46) suggests an analogy with scattering experiments, in particular dynamic light scattering (DLS), neutron scattering, and holographic relaxation spectroscopy (HRS). In

Figure 13 Scattering of a plane wave from a particle at $\mathbf{r}_j$ and the reference point (+)

the idealized scattering experiment an incident plane wave having the wave vector $\mathbf{k}_i$ of magnitude $2\pi/\lambda$ is scattered through an angle θ_s by suspended particles. The scattered wave is described by the wave vector $\mathbf{k}_s$ that has a different direction but the same magnitude as the wave vector of the incident wave. In DLS we are concerned with the relative phase ϕ_j of the electric field E_s of the light scattered by the j th scatterer at the detector. This phase angle depends on the path lengths and, as illustrated in Figure 13,

$$\phi_j = \mathbf{k}_i \cdot \mathbf{r}_j - \mathbf{k}_s \cdot \mathbf{r}_j = \mathbf{q} \cdot \mathbf{r}_j \quad (47)$$

where elementary trigonometry shows that $|\mathbf{q}| = (4\pi/\lambda) \sin(\theta_s/2)$. The quantity derived from DLS data is the reduced first-order correlation function $g^{(1)}(\tau)$ defined by

$$g^{(1)}(\tau) = \frac{\langle E_s^*(0) E_s(\tau) \rangle}{\langle |E_s(0)|^2 \rangle} \quad (48)$$

If the motions of the scatterers are independent and certain other conditions are satisfied, only ‘self-correlation’ terms are important and equations (47) and (48) can be combined to obtain:^{5, 61}

$$|g^{(1)}(\tau)| = \langle \exp\{i\mathbf{q} \cdot [\mathbf{r}_j(\tau) - \mathbf{r}_j(0)]\} \rangle \quad (49)$$

where $\langle \rangle$ represents an average over all scattering particles. This, of course, is equivalent to equation (43) for a uniform distribution of scatterers with τ in place of Δ . The discussion of DLS also applies to neutron inelastic scattering, except that the self-correlation function is available directly without assumptions about independent motions of scatterers from the neutron scattering function for the incoherent fraction.

In DLS the scattering angle determines the magnitude of $\mathbf{q}$ and $\sin(\theta_s/2)$ plays a role similar to that of the gradient area in NMR. Similarly, the diffraction spot in DLS is analogous to the spin echo in NMR. This analogy can be pursued to show why DLS and PFG-NMR measure different types of diffusion coefficient. The key to the difference is the condition necessary for there to be a signal. In the case of light scattering a perfectly uniform distribution of scatterers, as for example in a perfect crystal, cannot produce a diffraction spot since light

scattered by the different scattering centers will interfere and cancel at the detector. The way to get around this problem is to arrange the scatterers so that they behave as a diffraction grating and produce intensity at the desired scattering angle. That is what actually happens in a solution or suspension of particles. Instantaneous concentration fluctuations have Fourier components that scatter light in various directions. This is why a grainy pattern of twinkling speckles is observed when light from a laser beam is scattered by a solution onto a flat surface. The important point is that the concentration of scatterers must vary with position, and time-dependent concentration changes result from mutual diffusion in the presence of concentration gradients.

In NMR it is well known that a single 90° rf pulse cannot produce a spin echo for a uniform sample. After the FID there is complete interference and the isochromats do not refocus. A close analogy with the optical case is found in the STE experiment. Here the magnetization pattern, created prior to the third 90° pulse, plays the role of a 'diffraction grating'. The 90° rf pulse rotates the isochromats into the xy plane where they evolve under the influence of a gradient until an echo is formed. The vector addition problem is identical to that found for the electric field in small angle light scattering. However, STE formation does not require spatial variations in the concentrations of particles but rather in the spin polarization (or phases) of the nuclei. Therefore, PFG-NMR detects tracer diffusion. It is, of course, possible to measure mutual diffusion with NMR by creating a periodic concentration pattern, as discussed in Section 3.2.

HRS provides an even more obvious analogy with the STE experiment.^{10,62,63} In HRS two monochromatic laser beams are crossed at a small angle in a sample to form an interference pattern that in turn produces a volume hologram of photoproducts. In the low intensity limit the concentration of the j th photoproduct can be expressed as:

$$c_j(z, t) = \langle c_j \rangle + c_{1j} \cos(qz) \quad (50)$$

where $\langle \rangle$ represents an average over space and c_{1j} is the amplitude of the grating. The time evolution of the grating is monitored by a laser probe beam incident on the sample at the Bragg angle. In a heterodyne experiment where the diffracted light is mixed with a reference beam, the electric field of the diffracted light is determined and the amplitude of the grating can be mapped as a function of time. If photoexcitation changes optical properties and not hydrodynamic properties, this experiment permits tracer diffusion rates to be measured.

Analogies also appear in the spatial imaging of gratings. In the optical grating experiment a Fourier transformation of the electric field of the diffracted light with respect to the scattering angle yields an image of the diffracting grating. In the simplest case the diffraction spot is represented by a delta function at the angle θ_s and the grating is a cosine function. In the STE experiment an image of the magnetization grating can be obtained by reading out the stimulated echo in the presence of a constant gradient and Fourier transforming the signal with respect to time measured from the third 90° rf pulse. Images of transient magnetization gratings (TMGs) are useful for monitoring the spatial dependence of diffusion and flow.¹⁰ In the medical literature this method is known as 'spatial manipulation of magnetization' (SPAMM).⁶⁴

6 RESTRICTED DIFFUSION AND DIFFUSIVE DIFFRACTION

A significant fraction of NMR diffusion studies have been devoted to the restricted diffusion of fluids since Woessner's studies of porous materials with CW gradients.⁶⁵ PFG-NMR studies of restricted diffusion date from the pioneering work of Tanner and Stejskal.⁶⁶ Their procedure was to solve the diffusion equation with appropriate boundary conditions for $P(r | r', t)$ and to determine the echo amplitude by means of equation (43). Echo amplitudes have been derived for systems where diffusion is restricted by reflecting surfaces in the form of parallel planes, cubic cavities, cylinders, and spheres for steady gradients⁶⁷ and pulsed gradients.^{66,68} There is much current interest in the study of porous materials by means of PFG-NMR.

The spherical cavity provides an important model for restricted motion in pores and in biological cells and vesicles. This case was treated by Neuman⁶⁷ for a steady gradient assuming a Gaussian distribution of phases at the time of the echo, and the calculation was later extended by Murday and Cotts⁶⁸ to the pulsed gradient SE experiment. The pulsed gradient solution is shown in equation (51) for a sphere of radius R :

$$\ln[\psi(q)] = -2\gamma^2 g^2 \sum_{m=1}^{\infty} \frac{1}{\alpha_m^4 D (\alpha_m^2 R^2 - 2)} \times \left(2\delta - \frac{2 + x_m^{\tau-\delta} - 2x_m^\delta - 2x_m^\tau + x_m^{\tau+\delta}}{\alpha_m^2 D} \right) \quad (51)$$

Here $x_m = \exp[-(\alpha_m^2 D)]$ and α_m is the m th root of the equation

$$(\alpha_m^2 R^2 - 2) \sin(\alpha_m R) + 2\alpha_m R \cos(\alpha_m R) = 0 \quad (52)$$

The parameters τ , δ , and g are defined in Figure 2, except that here $\tau = \Delta$. In the short time limit ($\Delta \ll R^2/2D$), equation (51) gives $\psi(q) = \exp(-Dq^2\Delta)$ as expected for unbounded diffusion; in the long time limit ($\Delta \gg R^2/2D$), $\psi(q) = \exp(-q^2 R^2/5)$. Comparison of these results suggests that the effective diffusion coefficient in the long time limit is $D_{\text{eff}} = R^2/5\Delta$. This turns out to be precisely the mean square displacement $\langle Z^2 \rangle$ divided by 2Δ . The exact solution for $\psi(q)$ in the long time limit obtained by adapting results from the literature of heat diffusion is

$$\psi(q) = 9[qR \cos(qR) - \sin(qR)]^2 / (qR)^6 \quad (53)$$

The long time limit of equation (51) agrees with exact result for small values of qR and the deviation is only 0.29% at $qR = 1$.

It is instructive to investigate the long time limit in more detail. If the fluid has the initial density distribution $\rho(z_0)$, in the limit $\Delta \rightarrow \infty$ we expect that $P(z_0 | z_0 + Z)$ will equal $\rho(z_0 + Z)$. Therefore, the average propagator can be written as

$$\bar{P}(Z, \infty) = \int \rho(z_0) \rho(z_0 + Z) dz_0 \quad (54)$$

Figure 14 Echo amplitudes versus q^2 for pore glass. The data sets were obtained with $\Delta = 20$ (■), 40 (●), 70 (▲), and 110 (◆) ms. (q in this figure is defined as $1/\Delta$)⁷⁰

and $\bar{P}(Z, \infty)$ is just the autocorrelation function of the molecular density or the convolution of the density with itself. It is also easy to show that equation (45) takes the form

$$\psi_\infty(q) = \left| \int \rho(z_0) \exp(-iqz_0) dz_0 \right|^2 \quad (55)$$

Equations (45) and (54) show that the inverse Fourier transform of the echo intensity provides an image of the autocorrelation function of the density in real space.^{69,70} This is the origin of diffraction-like effects in NMR diffusion studies, an idea that has led to a powerful method for the investigation of the structure of porous materials. For example, a ‘pore glass’ consisting of water in the presence of monodisperse spheres gives the echo intensities versus q shown in Figure 14.⁷⁰ At short times there is little indication that a water molecule samples more than one pore, while at longer times the diffraction effect resulting from neighboring pores is clearly visible. A Fourier transformation of an echo curve gives an image of the autocorrelation function. Note that this type of imaging gives resolution several orders of magnitude higher than MRI, since intensity is provided by the entire sample rather than a small voxel; but the information is limited to average features of local structure rather than positions of individual molecules in space.

Other important restricted diffusion problems include motion near an attracting center, diffusion in the presence of permeable walls and surface relaxers, inhomogeneous initial magnetization, and the effect of surface to volume ratios on the time dependence of the average propagator. These topics have been reviewed elsewhere,²⁵ except for the last one involving microgeometry and surface relaxation, a topic of considerable current interest in connection with the determination of pore size distributions.^{71–73}

7 ANISOTROPIC DIFFUSION

Anisotropic environments are found in organized phases such as liquid crystals and zeolite crystallites. The description of diffusion in such systems requires the diffusion tensor $\mathbf{D}_{\alpha,\beta}$ in place of the scalar coefficient D . As a consequence, the flux defined in equation (1) depends on orientation and the right-hand side of equation (4) becomes $-\nabla \cdot \mathbf{D} \cdot \nabla P(\mathbf{r}_0|\mathbf{r}, t)$. The attenuation factors have the same forms as previously found except that $g^2 D$ is replaced by $\mathbf{g} \cdot \mathbf{D} \cdot \mathbf{g}$. Therefore, if D_x , D_y , and D_z are defined as the principal values of the diffusion tensor the attenuation factor has the form

$$\psi(\theta, \phi) = \exp[-q^2 (D_x \cos^2 \phi \sin^2 \theta + D_y \sin^2 \phi \sin^2 \theta + D_z \cos^2 \theta) \Delta] \quad (56)$$

where θ and ϕ indicate the orientation of the gradient with respect to the principal axes of the diffusion tensor. For an axially symmetric diffusion tensor with $D_x = D_\perp$ and $D_z = D_\parallel$, we find that the mean square displacement in the direction of the gradient is proportional to $D_\parallel \cos^2 \theta + D_\perp \sin^2 \theta$. This type of treatment is appropriate for D_2O partially oriented in the lamellar phase of potassium palmitate/ D_2O .⁷⁴ In this system water diffusion is relatively unrestricted parallel to the bilayers but is limited in the direction of the director.

Unfortunately, the organized systems of interest for PFG-NMR studies are likely to present problems because of severe dipolar and quadrupolar broadening. Both quadrupolar⁷⁵ and solid echoes⁷⁶ may be useful replacements for the Hahn echo in such cases. Also, a Waugh-type line-narrowing sequence, modified to permit refocusing in the presence of gradient pulses, has been used to measure the anisotropy of a diffusion tensor of liquid crystal molecules in smectic-A and smectic-C phases.⁷⁷ These and other examples of measurement of anisotropic diffusion have recently been reviewed by Callaghan.²⁵

8 CHEMICAL EXCHANGE INVOLVING DIFFUSING MOLECULES

Chemical rate processes are detected by NMR when nuclei exchange between sites characterized by different spin Hamiltonians.⁷⁸ It is also possible that the sites will have similar spin Hamiltonians but will differ in hydrodynamic properties. In such cases the one-dimensional NMR spectrum is unaffected by exchange, but diffusion measurements may reveal the exchange process and permit it to be studied. Examples include: (i) association equilibria in which molecules diffuse freely or in association with larger, more slowly diffusing particles; and (ii) samples composed of subregions that are characterized by different numbers of spins and different diffusion coefficients.

Consider an FT-PFG-NMR experiment of the SE or STE type on a sample in which nuclei in various ‘exchanging’ sites all contribute to the same NMR line. In the slow exchange limit where exchange between sites is unlikely during the diffusion time Δ the signal amplitude can be described by a sum of exponentials as shown in equation (38). At the other extreme where many exchanges occur during Δ , a single exponential decay is found with a weighted average diffusion

coefficient. For intermediate exchange rates in the absence of strong spin coupling a simple theory of exchange, based on Bloch equations with diffusion and exchange terms, can be used to describe the evolution of longitudinal magnetization during the diffusion sensitive time interval $T = \Delta$ with $\tau, \delta \ll \Delta$. In this formulation the ‘on resonance’ magnetization $M_n(r, \Delta)$ for the n th species with spatial coordinates r is described by

$$\frac{dM_n(r, T)}{dT} = -\frac{1}{T_{1n}}M_n(r, T) - \nabla \cdot \mathbf{J}_n(r, T) + \sum_m K_{nm}M_m(r, T) \quad (57)$$

where the rate constants are given by $k_n = -K_{nn}$ and $k_{nm} = K_{nm}$. The flux $\mathbf{J}_n(r, T)$ is defined by

$$\mathbf{J}_n(r, T) = -D_n \nabla M_n(r, T) + M_n(r, T) \mathbf{v}_n(r, T) \quad (58)$$

where D_n and $\mathbf{v}_n(r, T)$ are the diffusion coefficient and velocity for the n th species, respectively. The calculation of the signal is simplified by taking the spatial Fourier transform of equation (57) to obtain

$$\frac{dM_n(q, T)}{dT} = (i\Omega_n - R_n)M_n(q, T) + \sum_m K_{nm}M_m(q, T) \quad (59)$$

where

$$M_n(q, T) = \int \exp(-i\mathbf{q} \cdot \mathbf{r}) M_n(r, T) d\mathbf{r} \quad (60)$$

Here $R_n = 1/T_{1n} + D_n q^2$ is a relaxation term, and $\Omega_n = \mathbf{q} \cdot \mathbf{v}_n$ describes the change in phase angle that results from flow, but for this discussion $1/T_{1n}$ and Ω_n are neglected. These equations and their solutions in special cases have been discussed by Kärger et al.,⁶⁰ and similar equations have been derived and studied for nuclear magnetic relaxation in multiple phase systems.⁷⁹

Most attention has been focused on the two-site exchange case that can be solved exactly. The fast and slow exchange limits can be recovered from the solutions and useful simple equations can be derived for special cases, but in general one must resort to numerical solutions. Special problems may arise in the application of the exchange model to porous systems since the transport processes may not be adequately described by equation (59), samples may not be sufficiently uniform in properties including spin relaxation rates, and susceptibility differences may distort local magnetic fields. However, exchange in liquids is free of such complications and should be well described by equation (59).

Chemical exchange in liquid mixtures is of interest in connection with DOSY.⁵⁴ In order to simulate diffusion spectra with exchange, the ILT of $M_n(q, T)$ must be obtained. In the two-site case the inversion can be performed analytically, and whenever equations are available for $M_n(q, T)$ the Fourier transform method (q^2 replaced with $i\omega$) can be used to obtain the ILT. The important quantity is the mean number of exchanges N that occur during the diffusion time T . In the slow exchange limit ($N \ll 1$) the diffusion spectrum consists

of delta functions at the various diffusion coefficients, and as the exchange rate increases the spectrum evolves into a single Gaussian peak centered on the average diffusion coefficient. For example, if spins exchange between two sites (A and B) with populations p_A and p_B and diffusion coefficients D_A and D_B , respectively, the peak is centered at $\langle D \rangle = p_A D_A + p_B D_B$. The distribution of diffusion rates results from the sequences of N exchanges that occur during T and the fraction of the time that a spin occupies each site. A simple calculation for $N \gg 1$ of the number of independent sequences associated with each diffusion coefficient gives a Gaussian distribution with the square deviation $\sigma^2 = \Delta D^2 p_A(1 - p_A)/N$ where $\Delta D = D_A - D_B$. Therefore, the width of the distribution depends on the exchange rate and offers the possibility of measuring this rate.

The fast and slow exchange limits are frequently encountered and recognized, but the intermediate exchange region is difficult to identify. The amplitude of the diffusion spectrum is low in the intermediate region, and as T/N increases the linewidth decreases and becomes difficult to measure. It is also difficult to distinguish between polydispersity and exchange broadening. However, the diffusion time T can be varied, and it may be possible in some cases to determine exchange rates by means of PFG-NMR. In fact, plots of the attenuation factor Ψ versus q^2 have been used in special cases to estimate the mean lifetime in a site.⁶⁰ But it should be clear that measurements of diffusion coefficients in the slow and fast limits give no information about exchange rates.

9 LARGE GRADIENTS AND THE MEASUREMENT OF SMALL DISPLACEMENTS

The measurement of small diffusion coefficients ($D \leq 10^{-11} \text{ cm}^2 \text{ s}^{-1}$) requires large values of the ‘scattering vector’ q . Typically this is accomplished by increasing the amplitude of the gradient pulses. Modern gradient drivers for use with high-resolution spectrometers deliver 20–50 A for durations of a few milliseconds with pulse area matching to 10 ppm.⁴² The gradient coils, either Maxwell pairs or quadrupolar coils, then produce gradients of a few hundred gauss per centimeter.^{80,81} Much higher gradients have been reported, but usually at the cost of imperfect matching. However, even at the lower levels the pulsed gradient systems suffer from joule heating, vibrations, and pulse induced eddy currents in the metal components of the probe and neighboring magnet structures. Each of these problems can be minimized by special probe designs, but still the useful limit for stable gradient pulses appears to be approximately 10^3 G cm^{-1} in a narrow bore (5 cm) solenoid.

One way around the problem of gradient mismatch and sample motion is to accept phase variation from experiment to experiment and to correct the acquired data. A scheme to do this is called modulus addition using spatially separated echo spectroscopy (MASSEY), and the idea is as follows.⁸² A phase error resulting from gradient mismatch means that the magnetization helix is not exactly unwound at the echo time. Therefore, if the echo is read out in the presence of a small read gradient g_r , a coherent superposition will occur in the vicinity of the expected echo center. One should then Fourier transform the echo with respect to $\gamma g_r t$, where t is

measured from the beginning of the read gradient, and use the modulus spectrum to measure the echo amplitude. The procedure of Fourier transformation prior to signal averaging permits displacements in the range of 1–10 nm to be measured, but does lead to a loss in the signal-to-noise ratio.

In a very different approach Kimmich et al.⁸³ have reported diffusion experiments in the fringe field of a superconducting magnet. Gradients of up to 42 T m⁻¹ were obtained in a 4.7 T, 40 cm bore solenoid, and consistent results have been obtained in narrow bore solenoids. Thus, gradients of extremely high stability are obtained without heating, vibrations, and eddy currents. The supercon fringe field (SFF) experiment is remarkably easy to perform in any spectrometer system since one only needs the amplifier, receiver, and probe for the appropriate frequency in the fringe field. However, in its original form the SFF experiment has two major disadvantages. First, all frequency resolution is lost since the signal is acquired in the presence of the gradient. This is a serious loss, but useful information can still be obtained for specially selected systems. We note that successful experiments have been performed on polymer solutions and melts.⁸⁴ Second, the frequency gradient is approximately 2 MHz mm⁻¹, and a 1 μ s rf pulse only excites a layer 0.5 mm thick. This results in very poor filling factors and small signal-to-noise ratios.

Both SE or STE diffusion experiments are easy in the fringe field, but the STE experiment is more flexible. As illustrated in Figure 3, the gradient in the STE experiment is only effective for phase encoding and decoding during the time intervals τ_1 after the first and third rf pulses, and the result is identical to a pulsed gradient experiment with pulses of duration $\delta = \tau_1$. An estimate of the lowest accessible diffusion coefficient $D_{\min}$ can be made by demanding that the attenuation caused by diffusion be equal to that resulting from relaxation. The result of this calculation is

$$D_{\min} \simeq \frac{1}{\gamma^2 g^2} \frac{1}{\delta^3 (2/3 + T/\delta)} \left(\frac{T}{T_1} + \frac{2\delta}{T_2} \right) \quad (61)$$

If τ_1 and T are of the order of T_2 and T_1 , respectively, and $g = 42$ T m⁻¹, equation (61) gives $D_{\min} \approx 2 \times 10^{-20}/(T_1 T_2^2)$ in m² s⁻¹. An improved STE experiment that permits the effective gradient duration to be varied without affecting relaxation is shown in Figure 15.⁸⁵ The introduction of 180° pulses in the encode and decode intervals partially refocuses the magnetization and cancels part of the effective gradient.

While the gradient amplitudes achieved in SFF are accessible with pulsed field gradients, the freedom from complications

Figure 15 The five pulse STE sequence for SFF experiments. The effective gradient for encoding and decoding spatial positions has the duration δ ⁸⁵

and the absence of rise and decay times for gradient pulses makes SFF a very powerful technique. The shortcomings mentioned above are already being addressed. For example, small excitation volumes can be used to advantage by exciting nonoverlapping slices without having to wait for T_1 recovery. Also, shaped rf pulses can be used to permit different pulse lengths while maintaining the same bandwidth. The loss of resolution appears to be intractable unless the sample can be moved into a homogeneous field for data acquisition. A shuttle system of the type developed for zero field spectroscopy can satisfy this requirement for samples with $T_1 > 100$ ms.

10 DATA ANALYSIS AND POLYDISPERSITY

Data sets from PFG-NMR (SE and STE) experiments are usually in the form of a signal versus q^2 or $q^2 \Delta$. For a monodisperse sample a single exponential decay as shown in equations (27) and (29) is expected. The logarithm of the signal can be fit as a linear function, but this emphasizes noise as the signal approaches zero and complicates the problem of proper weighting factors for the data points. It is better to use a nonlinear regression method to fit the exponential function directly. The Levenberg–Marquardt method is popular for this purpose.⁸⁶

The problem may be much more difficult when more than one diffusing species contributes to the observed decay. The discrete and continuous distributions of diffusion coefficients as described by equations (38) and (42), respectively, were discussed in connection with automated analysis to obtain diffusion ordered spectra. The same analysis problem has played a major role in the development of dynamic light scattering and the extensive reviews can be found in the literature of DLS. Highly recommended sources are the analysis chapters in the monographs by Schmitz⁸⁷ and Chu⁴ and the recent review by Štěpánek.⁸⁸ In general, the analysis problem is intractable. Exact answers cannot be extracted from the data and sometimes a wide variety of parameter sets fits the data within experimental error. There are, of course, some special cases where accurate answers can be determined easily or where the limited information required to characterize a distribution can be measured quite directly.

The discrete two-component decay, i.e. equation (38) with $N_\lambda = 2$, requires two decay constants, two amplitudes, and perhaps a baseline. Analysis is easy only when the decay constants differ by a large factor, the amplitudes are comparable, and the signal-to-noise ratio is high. When the answers are not obvious from a log plot, nonlinear regression procedures are sometimes used, but the latter do not provide a reliable procedure for multicomponent exponential decays, even when the number of components is known. The problem is that initial guesses of the parameters are required, and these may determine the outcome. For objective conclusions about the answers or even about the intractability of the problem, it is essential that the analysis not be biased by the user. A reasonable alternative is to use the program DISCRETE, which determines initial parameters by a Fourier method and then applies the least-squares method.^{48,49} The program SPLMOD is similar but faster, and it permits the simultaneous analysis of multiple data sets.^{50,51}

The continuous case requires, in principle, an ILT to determine the distribution of diffusion coefficients. There

appears to be only one simple case. If the distribution is unimodal and the distribution is narrow, a direct cumulant analysis may suffice. This method, introduced by Koppel,⁸⁹ is based on the expansion of the exponential function in equation (42) about the average decay constant $\langle\lambda\rangle$. The result is

$$G(s) = \exp \left[-\langle\lambda\rangle s + \frac{\mu_2}{2!} s^2 - \frac{\mu_3}{3!} s^3 + \frac{(\mu_4 - 3\mu_2^2)}{4!} s^4 + \dots \right] \quad (62)$$

where

$$\langle\lambda\rangle = \int_0^\infty \lambda g(\lambda) d\lambda, \quad \mu_n = \int_0^\infty (\lambda - \langle\lambda\rangle)^n g(\lambda) d\lambda \quad (63)$$

A fit of equation (62) to the experimental data set, $G(s)$ versus s , by means of nonlinear regression typically yields $\langle D \rangle$ and $\mu_2 = (\langle D^2 \rangle - \langle D \rangle^2) / \langle D \rangle^2$ with reasonable accuracy. The higher moments are less reliable. The ratio $\mu_2 / \langle D \rangle^2$ is commonly used as an index of polydispersity; but, when this ratio exceeds 0.3, equation (62) is not justified.

When broad or multimodal distributions are expected, general ILT analyses are required. Seven schemes have recently been compared by Štěpánek.⁸⁸ The most widely used methods are constrained regularization (CONTIN), nonlinear regularization (REPES), maximum entropy (MEM), and exponential sampling. Prospective users should study the reviews to become familiar with the types of artifacts characteristic of these methods. Also, it is strongly advised that simulated data similar to the data of interest be analyzed to obtain experience with limitations of the analyses. When noise is present, the information content of the PFG-NMR data sets is simply not sufficient to provide an exact image of the distribution. One must be satisfied with a reasonable estimate rather than no solution at all.

11 MASS AND SIZE DISTRIBUTIONS FROM NMR DIFFUSION DATA

The PFG-NMR data set $G(s)$ collected at a specific chemical shift for a polydisperse sample has the form (see Section 4.1):

$$G(s) = \int_0^\infty g_\kappa(\kappa) \exp[-D(\kappa)s] d\kappa \quad (64)$$

If $\kappa = D$ then $D(\kappa) = D$ and equations (64) and (42) are identical, but equation (64) is more general since κ may represent another molecular parameter of interest, e.g. molecular radius R or molar mass M . For example, the ILT of $G(q^2)$ gives $g_D(D)$, but $g_M(M)$ the distribution function for molar mass may be of interest. Equation (64) indicates that the normalized distribution for molar mass is given by $g_M(M) = g_D(D) |dD/dM|$.⁴ For linear polymers this transformation can be carried out with the assumption that $D(M) = KM^{-\alpha}$, where K is a constant. Here α ranges from 0.6 for dilute solutions to 2.0 for melts when the ‘reptation’ model holds.⁹⁰ However, this treatment ignores possible spin relaxation effects that may depend on the mass. In general, the distribution functions should include a relaxation factor, e.g. $g_M(M)$ becomes $A_0(M)g_M(M)$, where $A_0(M)$ depends

on T_1 and T_2 . The small molecules tend to have longer relaxation times and, therefore, contribute disproportionately to the measured diffusion coefficient. Therefore, the neglect of $A_0(M)$ leads to higher apparent diffusion coefficients.

Unfortunately, equation (64) is not always appropriate. A number of experimental studies of polymer mixtures have found essentially exponential attenuation curves and, therefore, much less indication of polydispersity than predicted.^{91,92} The important point is that equation (64) only holds when the diffusion rate of a polymer molecule is independent of the lengths of the neighboring polymer chains.⁹³ This condition is satisfied in very dilute solutions⁹⁴ and in the melts when diffusion can be described by the ‘reptation’ model.⁹⁰ Otherwise, little information can be obtained from $G(s)$ about $g_M(M)$. The averaging effect resulting from interactions with neighbors has been called ‘microscopic’ averaging.⁹²

Another aim of diffusion studies is to size particles, i.e. to determine $g_R(R)$. As shown above $g_R(R)$ can be obtained from $g_D(D)$ if the relation between D and R is known. For spherical particles equation (7) with appropriate corrections for volume fraction can be assumed and $g_R(R)$ can be derived. However, this distribution is weighted by the number of nuclei contributing to the signal, i.e. the number of nuclei with diffusion coefficients in the range D to $D + dD$. The number of particles in the range D to $D + dD$ may be the quantity of interest, and these distributions can be related if the number of nuclei can be determined as a function of R . For example, for vesicles the number of molecules in the bilayer increases roughly with R^2 while the number of molecules entrapped in the aqueous cavity increases with R^3 .⁵⁶ Therefore, the unnormalized distribution function for the number of nuclei associated with radii in the range R to $R + dR$ is proportional to $R^n g_R(R)$, with $n = 2$ or 3 depending on the source of the signal. Also, the relaxation factor $A_0(R)$ is important here since T_2 is short for bilayer protons and depends on R through the rotational correlation time. The result is that the uncorrected diffusion coefficients determined from bilayer signals are much higher than those obtained with signals from molecules entrapped in the aqueous cavity. In addition, the microscopic averaging effect mentioned above may reduce the effect of polydispersity on the observed signals. All of these problems are compounded because data inversion methods often yield inaccurate estimates of $g_R(R)$.

Similarities between NMR and DLS analyses have been noted, but it should be kept in mind that different kinds of averaging processes are involved. When relaxation can be ignored NMR intensities depend on the number of nuclei involved in the resonance and this number may be proportional to the molecular weight of a molecule, the volume of an entrapped fluid, etc. In DLS the intensity is proportional to the number of scatterers, but each scatterer is weighted by the square of the number of electrons. In some cases the number of electrons is proportional to the mass and to the volume of a molecule. This is the origin of the well-known rule that scattering from a particle is proportional to the square of its volume. Therefore, in the limit of infinite dilution where tracer and mutual diffusion coefficients are equal, NMR and DLS may still give different average diffusion coefficients for polydisperse samples. Also, as a practical matter, PFG-NMR data sets usually have fewer points and lower signal-to-noise ratios than data sets obtained in DLS.

12 LITERATURE SOURCES FOR NMR DIFFUSION MEASUREMENTS

The most complete, up-to-date treatment of translational dynamics and its study by NMR is found in the book by Callaghan.²⁵ The experimental and theoretical aspects of diffusion in liquids are treated in the monograph by Tyrrell and Harris,² and Crank's book¹ is still the standard reference for the mathematics of diffusion. The principles and applications of PFG-NMR have been reviewed by Kärger et al.,⁶⁰ and Stilbs³⁹ has provided a detailed review of FT diffusion studies. NMR studies of diffusion in polymer systems have been reviewed by von Meerwall.^{95,96} Wade⁹⁷ has reviewed lateral diffusion in lipids including NMR measurements, and Chachaty⁹⁸ has reviewed NMR relaxation and diffusion studies of micellar solutions. Molecular diffusion in NMR imaging has been reviewed by Le Bihan⁹⁹ (note that the references in this review incorrectly replace *Phys.* with *Physiol.* in several places). Multiple-quantum methods including sensitivity to gradients and use in diffusion studies have been reviewed by Norwood.¹⁰⁰

1 INTRODUCTION

High resolution NMR spectroscopy is one of the most powerful tools available for chemical structure elucidation. The great majority of high resolution NMR experiments are carried out on more or less pure materials, in which the signals of a single species dominate. NMR has until recently been much less widely used in the study of mixtures, but two techniques are changing this. The first is HPLC-NMR, in which NMR experiments are performed directly on the eluent stream from a chromatography column, in either continuous- or stopped-flow mode. HPLC-NMR is capable of handling complex mixtures, and offers great flexibility through the use of different stationary and mobile phases, but requires special hardware and is expensive both in instrument time and in solvent consumption. In the second, diffusion-ordered spectroscopy (DOSY), the results of pulsed field gradient spin echo experiments are analyzed to determine diffusion coefficients for the individual signals in a spectrum, and hence to distinguish between the signals of different components in a mixture. In most applications, two- or three-dimensional spectra are synthesized in which signals are dispersed in one dimension according to their diffusion coefficients. DOSY uses standard spectrometer hardware and sample handling, requiring only the additional software for data analysis and spectrum synthesis; the field has been authoritatively reviewed by Johnson.¹

DOSY and HPLC-NMR may be viewed as analogues, DOSY effecting a virtual separation as opposed to the true physical separation used by HPLC. The versatility that changes in stationary and mobile phase afford when separating substances by HPLC is to some extent paralleled by the possibility of manipulating the relative diffusion coefficients of different species by changing solvent, or by adding agents to bind species preferentially. The two techniques are largely complementary, HPLC-NMR generally being the more powerful but slower and more expensive technique. In principle it

would be possible to achieve higher resolution by combining stopped-flow HPLC-NMR with DOSY than either technique can provide in isolation.

Figures 1 and 2 illustrate some of the basic principles of DOSY. A series of measurements is made of pulsed field gradient stimulated echo spectra (Figure 1), in which diffusion causes signals to be attenuated. Fitting the signal peak heights as a function of gradient pulse area to the theoretical Gaussian form allows a diffusion coefficient and a standard error to be calculated for each peak in the spectrum. A two-dimensional diffusion-ordered spectrum can then be synthesized (Figure 2) in which the normal spectrum (top) is used to determine the horizontal (chemical shift) domain lineshape for each peak, and the diffusion coefficient and standard error are used to define the position and width of a Gaussian lineshape in the vertical (diffusion) domain. All signals for a given molecule should then appear in a horizontal line, at the same diffusion coefficient D ; cross-sections through the 2D spectrum at different values of D then separated subspectra for the different species in a mixture. This simple and effective approach is however restricted to the high resolution case where peaks are well-resolved in the chemical shift domain: where signals overlap in the normal spectrum, analysis can be much more problematic.

The name DOSY deliberately invites comparison with 2D NMR methods such as COSY (correlation spectroscopy) and NOESY (nuclear Overhauser effect spectroscopy). There is however an important distinction to be drawn between the true 2D techniques, in which the positions of signals in the indirectly detected frequency domain (F_1) are encoded as frequencies of amplitude or phase oscillation as a function of the evolution time t_1 , and DOSY, in which the positions of signals in the diffusion domain must be determined from the rate with which signal amplitude decreases as the strength of the applied magnetic field gradients is increased. F_1 frequencies in COSY etc. may be straightforwardly and unambiguously obtained by Fourier transformation of the signal oscillations as a function of t_1 (as well as by more sophisticated techniques such as linear prediction, maximum entropy or the filter diagonalization method), but there is no such general way to invert the corresponding experimental data in DOSY experiments. The Fourier transform is highly effective at unraveling superimposed oscillations, which may be treated as complex exponentials, but unfortunately the corresponding method for superimposed real exponential decays, the inverse Laplace transform, is numerically intractable.

DOSY therefore is forced to rely on simplifying approximations when attempting to interpret signal decay in terms of diffusion. By far the most common approximation is to assume, as in Figure 2 above, that each signal originates from a single species; this can allow very accurate estimation of diffusion coefficient, but risks misleading the experimenter if a given signal actually contains contributions from more than one species. Where two signals with different diffusion coefficients overlap, fitting the data to the form expected for a single decay will yield a compromise diffusion coefficient intermediate between the two true values. It seems unlikely that a practical, general solution will be found to the problem of unambiguously inverting an experimental decay of signal amplitude with gradient pulse area into an accurate distribution of signal strength as a function of diffusion coefficient, but a number of useful approximations are available.

Figure 1 500 MHz ^1H pulsed field gradient spin echo spectra for a mixture of acetone (A), choline (C) and DSS (2,2-dimethyl-2-silapentane-5-sulfonate sodium salt, D) in D_2O ; a signal is also seen for residual H_2O (W). 30 spectra were acquired using the PFGLED sequence of Figure 3(b) using gradient strengths incremented linearly from 0.5 to 15 G cm^{-1}

Figure 2 DOSY spectrum calculated from the data of Figure 1

DOSY is, in essence, nothing more than a new form of data presentation applied to a much older family of techniques, that of pulsed field gradient measurements of diffusion coefficient. However, by highlighting the use of such methods for the analysis of mixtures and focusing attention on some of their limitations, DOSY has led both to significant improvements in techniques for diffusion measurement and to a much wider range of applications.

2 HISTORICAL BACKGROUND

It was recognized very early in the development of NMR that diffusion contributes to the attenuation of spin echo

signals when experiments are performed in an inhomogeneous magnetic field. Spins that move through a spatially-varying magnetic field during a spin echo experiment will suffer changes in Larmor frequency, leading to changes in signal phase that depend on the motion undergone. Diffusive motion will lead to a distribution of different signal phases, and hence to a diminution in net signal. This principle has been extensively exploited, and NMR remains one of the most widely-used of techniques for measuring diffusion.^{2,3}

Experiments carried out using a static field which remains inhomogeneous throughout are limited in application, as the line broadening caused by the field inhomogeneity leads to signal overlap and reduces signal-to-noise ratio. The introduction

of pulsed magnetic field gradients allowed spin echo signals to be measured under high resolution conditions, retaining high sensitivity and allowing signals with different Larmor frequencies to be distinguished. Pulsed field gradient spin echo experiments come in a variety of forms, but all share the same basic features. After initial excitation, the evolution of the spins falls into three distinct phases: a defocusing period, in which field gradient pulses are used to give each spin a position-dependent phase; a delay, during which diffusion takes place; and a refocusing period, in which gradient pulses are applied to reverse the original phase encoding. For a single rectangular field gradient pulse of width δ and amplitude G , the extent of defocusing or refocusing produced is described by the gradient pulse area $q = \gamma\delta G$; an effective gradient pulse area may be defined for more complex sequences of gradient pulses. Spins that experience no net movement during the diffusion period refocus exactly, but where diffusion takes place, a distribution of signal phases results and the net magnetization is therefore attenuated. The net signal attenuation as a result of unrestricted diffusion shows a Gaussian dependence on q (an exponential dependence on q^2):

$$S(q) = S(0) \exp[-D \Delta' q^2] \quad (1)$$

where D is the diffusion coefficient, and the effective diffusion time Δ' is the time Δ between the midpoints of the defocusing and refocusing periods less a small correction for diffusion during the gradient pulses. It is important to choose values for q^2 that give an accurate record of diffusional attenuation for all species of interest, without wasting time acquiring spectra which are uninformative.¹

The idea that pulsed field gradient echo spectra could be used for the analysis of mixtures dates back at least to the 1981 work of Stilbs,⁴ but the concept of a diffusion-ordered spectrum was only introduced by Johnson in 1992.⁵ Two distinct strands may be distinguished in the development of DOSY: high resolution DOSY, in which relatively complex mixtures can be analyzed with good diffusion accuracy using well-resolved spectra where the majority of peaks arise from a single species, and low resolution DOSY, in which the overlap or complete superimposition of signals limits the reconstruction of the diffusion dimension of the DOSY spectrum to a relatively low resolution. Between these two poles a variety of approaches may be used to constrain the analysis in order to maximize the amount of chemically useful information to be obtained from the experimental data.

3 DATA ANALYSIS

3.1 High Resolution DOSY

The simplest approach to analyzing the results of DOSY experiments is to assume that each individual peak in the NMR spectrum arises from a single species, and hence has an amplitude which varies with gradient pulse area according to equation (1). In simple mixtures with well-resolved signals this is straightforward, and gives the maximum interpretable information for a minimum of effort. The basic data processing follows the pattern described briefly in the Introduction. After measurement, experimental free induction decays are weighted and Fourier transformed as normal; where most signals have

the same common linewidth, mild resolution enhancement may be useful. Careful baseline correction is then carried out, to minimize distortions of the diffusion spectrum caused by instrumental shortcomings and crosstalk between signals. Peak heights are tabulated as a function of gradient pulse area for each peak identified in the spectrum, and two-parameter exponential least squares fitting as a function of q^2 is carried out. This yields an apparent diffusion coefficient and a standard error for each peak, which may then be used in synthesizing a DOSY spectrum. For each peak j in the normal spectrum (for convenience, the spectrum with lowest q is generally used) a two-dimensional peak is constructed which has the same shape in the NMR dimension as that $S_j(F)$ in the normal spectrum, a volume proportional to the peak height in the normal spectrum, and a Gaussian shape in the diffusion dimension which is centered on the fitted diffusion coefficient D_j and has a width determined by the standard error σ_j . The final 2D DOSY spectrum is then the sum of N such 2D peaks:

$$S(D, F) = \sum_{j=1}^N \frac{S_j(F)}{\sqrt{2\pi}\sigma_j} \exp\left[-\frac{(D - D_j)^2}{2\sigma_j^2}\right] \quad (2)$$

Several refinements of this basic approach are possible. Even the best available spectrometer hardware is unable to switch as rapidly as required between a field gradient pulse and high resolution conditions, with the result that spectra show small distortions because of the slow recovery of the main magnetic field B_0 to maximum homogeneity. These distortions may be corrected by reference deconvolution⁶ (qv) if there is a suitable reference signal available in the spectrum. To the normal requirement that the reference signal should be a strong, well-resolved singlet, must be added the stipulation that the reference material should preferably diffuse no more rapidly than the slowest of the species under study, so that the reference signal remains strong in all the experimental spectra. One candidate for such a material in non-polar solvents is polydimethylsiloxane. In practice, 2–3 fold improvements in diffusion resolution may readily be obtained using reference deconvolution.

Another common instrumental shortcoming that reduces resolution in the diffusion domain of a DOSY spectrum is non-uniformity of the pulsed linear field gradient, i.e., the presence of gradients of higher orders than one. Variations of 10% across the active volume of the probe are common, with larger discrepancies outside the observe coil. The effect of such variation is make the signal attenuation dependence on q deviate from a Gaussian: effectively the decay becomes the sum of different Gaussians from different regions of the sample. For signals that are only mildly attenuated this is of little consequence: relatively clean Gaussian behavior is seen, corresponding to a gradient strength averaged over the sample. Where, however, signals undergo severe attenuation, the weaker gradient in some parts of the sample leads to significantly stronger signals than expected at high nominal gradient strengths. These deviations from Gaussian behavior lead to an increased error in the fitting process, and are one of the causes of the common observation that DOSY signals are broader in the diffusion domain at high diffusion coefficient. The loss of resolution can be reduced by empirically adjusting the apparent values of q^2 to force the experimental signal decay to adopt the expected Gaussian shape: this improves

the accuracy of fit, and hence the accuracy with which relative diffusion coefficients are determined, at the expense of a small loss in absolute accuracy. A much more effective solution, however, is to determine the form of the distribution of signal strength as a function of gradient strength, and then use this information to calculate the predicted form of the signal attenuation curve as a function of q^2 . This may conveniently be done by mapping the experimental distributions of signal strength and gradient strength as functions of position within the sample, and then integrating over the sample to find the overall signal attenuation curve. Fitting to this function, which may conveniently be represented as the exponential of a power series, rather than to a Gaussian, then gives much better statistics for signals that experience strong attenuation. The benefits are particularly apparent when studying mixtures with a wide range of diffusion coefficients, since at high q the signal intensities of rapidly diffusing species will be dominated by contributions from the regions of the samples experiencing the lowest gradients.

Data processing strategies in DOSY depend on the nature of the sample, the characteristics of the spectrum, and the signal-to-noise ratio of the NMR data. Where resolution is good but signal-to-noise ratio poor, as for example with ^{13}C or ^{29}Si , there is little need for baseline correction and little advantage in using reference deconvolution. Conversely, for ^1H systems with very high signal-to-noise ratios, baseline correction is important and the improvement in diffusion resolution obtainable by combining reference deconvolution and gradient mapping can approach an order of magnitude.

3.2 Low Resolution DOSY

The problem of identifying an arbitrary distribution of signal intensity as a function of diffusion coefficient (a "diffusion spectrum") from measurements of signal attenuation as a function of gradient pulse area is one that has already been intensively studied in a different context, that of dynamic light scattering. Given the absence of a method for computing accurate inverse Laplace transforms from experimental data, the challenge is to use suitable approximations, constraints and prior knowledge to enable realistic diffusion spectra to be constructed. For polydisperse systems, where there is a continuous distribution of diffusion coefficients, only very general constraints can be applied, typically that the diffusion spectrum remain positive and that it be as simple and featureless as is compatible with the experimental data. This conservative approach minimizes the risk of misinterpretation, but yields large uncertainties in the diffusion coefficients of any monodisperse components in a mixture. The two approaches that have proved most successful in DOSY analysis of polydisperse systems are CONTIN⁷ and maximum entropy.⁸

3.3 Intermediate Approximations

Many mixture analysis problems lie between the two extremes of a fully-resolved and an unresolved NMR spectrum. Some spectral lines are well-resolved, others are the sum of two or more components, which may be partially resolved. Under such circumstances low resolution DOSY has little to offer unless the system exhibits only a few diffusion coefficients which are of very different magnitudes. The straightforward monoexponential analysis as a function

of q^2 described above is more successful in providing useful chemical information, since where two signals with different diffusion coefficients contribute to a given peak the apparent diffusion coefficient will be intermediate between the two values. Since the effects of overlap are simple where only two signals are involved, DOSY spectra with a minority of signals overlapping are relatively straightforward to interpret, but the ability to extract a complete subspectrum for a given diffusion coefficient is lost.

Between the Procrustes bed of a single exponential fit and the open-ended analyses of CONTIN and maximum entropy lie a range of methods designed to fit the experimental data to more or less constrained models, using prior knowledge of the likely form of the diffusion spectrum to allow the maximum of useful information to be extracted from the experimental data. In moderately crowded spectra the majority of cases of overlap will only involve two signals, so a logical first step is to replace monoexponential fitting with biexponential. Simple four parameter biexponential fitting can be quite satisfactory provided that the two diffusion coefficients differ by a factor of two or more, but the generation of initial guesses for the iterative fitting risks introducing bias. A safer solution is the general package for multiexponential fitting SPLMOD (SPLine Model), which has been used successfully⁹ for DOSY by incorporating pragmatic rules for the rejection of spurious fits. A variety of more sophisticated approaches to analyzing multiple overlapping exponentially decaying spectra have been proposed, including the DECRA (direct exponential curve resolution algorithm),¹⁰ MCR (multivariate curve resolution)¹¹ and CORE (component resolved NMR)¹² methods, but have yet to be widely applied.

4 EXPERIMENTAL METHODS

4.1 Homonuclear 2D DOSY

The earliest experiments used the basic Carr-Purcell pulse sequence in the presence of a continuous field gradient. The introduction of pulsed field gradients has already been mentioned; the next improvement was the shift to using a stimulated $(90 - \tau - 90 - \Delta - 90 - \tau)$ rather than a Carr-Purcell $(90 - \tau - 180 - \tau)$ echo sequence. This carries a factor of two penalty in sensitivity, since on average only half of the initial transverse magnetization is refocused in a stimulated echo, but minimizes the time for which the magnetization remains transverse. This is of value for systems where T_2 is significantly shorter than T_1 , but is particularly useful for systems with homonuclear scalar coupling. Restricting the time that magnetization spends in the transverse plane minimizes the impact of J modulation, and hence avoids the introduction of multiplet phase errors. Since high resolution DOSY generally relies on peak heights as a guide to signal intensity, any dispersion mode character to the experimental lineshape greatly increases the risk of signal overlap, and hence of crosstalk between adjacent peak heights and distortion of the diffusion spectrum.

The parent pulse sequence for most DOSY experiments is the pulsed field gradient stimulated echo (PFGSTE) sequence of Figure 3(a), in which the delays τ are just long enough to encompass the transmitter pulse fall time, the width δ of the gradient pulse, and the recovery time for the gradient pulse.

Figure 3 Radiofrequency (RF) and gradient (G) pulse sequences for DOSY: (a) pulsed field gradient stimulated echo (PFGSTE); (b) pulsed field gradient longitudinal echo delay (PFGLED); (c) gradient compensated stimulated echo sequence (GCSTE); (d) bipolar pulse pair stimulated echo (BPPSTE); (e) one-shot BPPSTE; (f) convection compensated double stimulated echo. 90° pulses are indicated by narrow rectangles in the RF traces and 180° by broad. Purge/homospoil pulses as an alternative or adjunct to phase cycling are indicated with dotted lines; up/down arrows indicate gradient pulse amplitudes that are increased/decreased to obtain increased diffusional weighting of signals. In the defocusing and refocusing periods, the spacing between RF pulses is given by the sum of the gradient pulse width δ and the gradient recovery delay τ_R , as shown for sequence (a)

If the diffusion delay Δ is defined as the time between the midpoints of the two gradient pulses, the correction to the diffusion time for diffusion during the gradient pulses is $-\delta/3$, giving $\Delta' = \Delta - \delta/3$ and the familiar attenuation expression

$$S(q) = S(0) \exp[-Dq^2(\Delta - \delta/3)] \quad (3)$$

This basic sequence is perfectly serviceable for many purposes, but is capable of considerable improvement. Two problems which are of particular importance under high resolution NMR conditions are those of slow main field recovery from the gradient pulses, causing distortion of the early part of the free induction decay, and interference with the deuterium field frequency lock. In general the former effect is brief, giving a broad distorted base to lines, and the latter relatively long-lived, giving sharp but “unphaseable” lineshapes.

The problem of main field disturbance, usually due to eddy currents induced in the probe and magnet metalwork, is much less severe in modern instruments, which have self-shielded (“actively shielded”) gradient coils. These minimize magnetic flux leakage outside the gradient coil, and hence give rise to much weaker eddy currents. For probes with unshielded gradient coils, a very effective way to circumvent problems from eddy currents is to add a z-filter to the stimulated echo sequence, storing the refocused magnetization for some tens of ms until the field is stable. Such a LED (longitudinal echo delay)¹³ step may be included in a variety of DOSY pulse sequences; the simplest is the PFGLED sequence of Figure 3(b).

A more general solution to the problem of eddy currents in modern high resolution spectrometers, which also deals with the problem of gradient pulses suppressing the deuterium lock signal and hence introducing slow B_0 shifts, is to use bipolar pairs of field gradient pulses. Using closely-spaced matched pairs of gradient pulses of opposite polarity cancels eddy current effects to first order, and refocuses the deuterium lock signal in a gradient echo. Such opposed pulse pairs may have one partner outside the defocusing/refocusing periods, or have both pulses within the defocusing/refocusing period but bracketing a 180° radiofrequency pulse. Sequences using the latter construct are generally referred to as bipolar sequences, since the diffusion encoding is carried out by the bipolar pulse pair; such sequences have a number of advantages. In second-order scalar coupled systems, relaxation effects can lead to zero quantum coherence causing phase errors in simple stimulated echo pulse sequences; by refocusing chemical shifts, bipolar sequences avoid exciting such coherences and hence do not suffer from phase errors in strongly coupled multiplets. Bipolar sequences also reduce contributions to diffusion-encoding from static background field gradients; these are not a problem under high resolution conditions, but in heterogeneous systems with strong internal field gradients caused by magnetic susceptibility differences they can complicate matters significantly. Adding balancing gradient pulses to the PFG-STE sequence gives the gradient compensated stimulated echo (GCSTE) sequence of Figure 3(c), which is a good general purpose sequence for systems lacking strong coupling; in the latter case the bipolar pulse pair stimulated echo (BPPSTE) sequence of Figure 3(d) is preferable.

With all pulse sequences for high resolution DOSY it is important to ensure that the desired coherence transfer pathway is followed. At first sight this might seem unimportant for a

sequence such as PFGSTE, since the gradient pulses might be expected to suppress the coherence transfer antiecho. However, even with strong gradient pulses the attenuation envelope for rejected signals only decays as the inverse of the pulse area. Small amounts of unwanted signal can therefore survive the pulse sequence, causing small intensity and phase anomalies and distorting the resultant diffusion spectrum. For the best results with PFGSTE-based sequences it is therefore important to use phase cycling. With BPPSTE, the issue is more critical, since without phase cycling any magnetization that does not experience perfect 180° pulses during the defocusing and refocusing periods will form a gradient echo over the relevant period and will not experience significant diffusional attenuation.

Where speed of measurement is important – and useful DOSY data can be obtained in as little as 30 s – a purge/homospoil pulse may be used in the diffusion delay to enforce zero coherence order in this period, and in bipolar sequences the positive and negative gradient pulses may be unbalanced in order to dephase magnetization not refocused by the 180° pulses. A final refinement is to add dummy pulses, where gradient amplifier duty cycle permits, before the start of a pulse sequence. These may be ramped down in amplitude as the diffusion-encoding pulses are ramped up, in order to keep the net energy dissipated the same for each transient; the pulses precondition the gradient amplifier and coil, and reduce gradient pulse area mismatch problems. A bipolar sequence which incorporates all three of these modifications and is suitable for “one-shot” (single transient per gradient value) use is shown in Figure 3(e).

The limitations imposed by non-uniformity of the pulsed field gradient are most effectively dealt with as described in Data Analysis, since this retains full sensitivity and resolution in the NMR data. A much simpler method of reducing the impact of gradient non-uniformity is to restrict the active volume of the sample to the most homogeneous region of the gradient (i.e., the region where the applied gradient is closest to linear). This may be achieved either by using selective excitation in the presence of a field gradient to select just a slice of the sample, or by physically restricting the length of the sample. In the former case care must be taken to avoid spurious echo phenomena, while in the latter case even the best susceptibility matching still results in a substantial degradation of the NMR lineshape.

A more serious limitation on DOSY measurements is the requirement that the motion of the spins in the sample be dominated by diffusion. Typical high resolution DOSY experiments use diffusion times Δ of a few tenths of a second, so for small molecules the mean square displacement over the timescale of the experiment is about $20 \mu\text{m}$. Coherent motion of the spins with a velocity of the order of $1 \mu\text{m s}^{-1}$ is thus sufficient to interfere with diffusion measurements even for small molecules; studies on macromolecules, and on nuclei with low magnetogyric ratio, can be vitiated by much slower motion (of the same order as continental drift). There is thus a severe potential problem of convection when attempting to use DOSY at temperatures above or below room temperature.

Where mobile solvents such as methanol or acetone are used, the onset of convection in a normal NMR tube with commercial probes is typically only a few degrees away from the quiescent sample temperature. The first sign of convection is usually the appearance of small phase errors

at higher gradient strengths; for low velocities, the phase error is proportional to the product of the gradient pulse width, diffusion time and gradient amplitude. Unfortunately, apparent phase errors are a common symptom of other instrumental problems, including lock disturbance, slow B_0 recovery, and gradient pulse area mismatch. The onset of convection can be delayed by using a capillary tube, particularly if the capillary is surrounded by a mobile (but NMR-silent) solvent, since the convection of the outer liquid helps reduce the temperature gradient along the capillary sample. A more general solution to the problem of coherent motion of the spins during DOSY experiments is to build velocity compensation into the pulse sequence. The sequence of Figure 3(f) uses a double stimulated echo¹⁴ to refocus the phase gradient caused by coherent motion. Such sequences, which can be extended by analogy with sequence 3(e) to avoid lock disturbance and hence give improved lineshapes, allow DOSY measurements to be performed over a much wider temperature range.

4.2 Heteronuclear 2D DOSY

The principal factor limiting the application of DOSY to the analysis of complex mixtures is the requirement that spectra be well-resolved if good diffusion resolution, and hence good discrimination between mixture components, is to be obtained. One way to improve resolution is to select for observation a nucleus such as carbon-13 that has a relatively high ratio of chemical shift dispersion to linewidth. Unfortunately there is a double price to pay on moving from protons to carbon-13, in the form of greatly reduced signal-to-noise ratio and a four-fold decrease in sensitivity to field gradients. The latter problem can be eliminated, and the former

somewhat reduced, if the carbon-13 signals measured are the result of polarization transfer from protons. Combining a proton pulsed field gradient stimulated echo sequence with INEPT (insensitive nuclei enhanced by polarization transfer) or DEPT (distortionless enhancement by polarization transfer) transfer to carbon-13 allows carbon signals to be measured which enjoy the usual signal enhancement and recycle time advantages of polarization transfer techniques, and show the same sensitivity to diffusion as proton signals. DOSY-DEPT and DOSY-INEPT¹⁵ can, where sensitivity permits, be very effective mixture analysis tools. One complication is the need to keep power deposition in the sample from decoupling to a minimum, since quite modest decoupling powers are sufficient to generate convection in mobile solvents.

4.3 3D DOSY

A more general approach to improving spectral resolution in DOSY is to extend experiments into a further spectral dimension. 3D DOSY experiments involve the measurement of a series of conventional two-dimensional spectra with increasing diffusion weighting, typically by prepending a pulsed field gradient stimulated echo sequence to the preparation period of a normal 2D experiment. Cross- and diagonal-peak volumes are then fitted to extract diffusion coefficients and standard errors and a 3D DOSY spectrum synthesized in a manner exactly analogous to 2D DOSY. DOSY-COSY,¹⁶ DOSY-NOESY¹⁷ and DOSY-TOCSY (total correlation spectroscopy)¹⁸ experiments have all been described, although most applications have been restricted to labeling 2D peaks with diffusion coefficients rather than carrying out the synthesis of a full 3D spectrum. The highest

Figure 4 400 MHz proton DOSY spectrum of a mixture of quinine (Q), geraniol (G) and camphene (C) in deuteriomethanol; signals are also seen for HDO (W) and TMS (T)

net resolution technique reported to date is DOSY-HMQC (heteronuclear multiple quantum coherence),¹⁹ which disperse signals according to proton shift, carbon-13 shift and diffusion coefficient.

5 EXAMPLES

Figure 4 shows a typical high resolution proton 2D DOSY spectrum for a simple mixture, illustrating some of the strengths and weaknesses of DOSY as a tool for the analysis of simple mixtures. The sample, a mixture of quinine, geraniol and camphene in deuteriomethanol, also contained TMS (tetramethylsilane) as reference, and residual water and monoproliomethanol. Spectral data were acquired at 400 MHz

using the GCSTE sequence of Figure 3(c); 10 spectra of 16 transients covering the range 0.6–10 G cm⁻¹ in equal steps of gradient squared were measured with a diffusion time Δ of 0.5 s and gradient pulse widths δ of 2 ms, in a total time of 45 min. These parameters were chosen to give only modest (ca. 50%) attenuation for the signals of the slowly-diffusing quinine, in order to ensure that there was sufficient TMS signal for reference deconvolution at the higher gradient strengths. Spectra were processed with reference deconvolution based on the TMS line to give a Lorentzian lineshape of 1 Hz at half height, baseline corrected using cubic spline interpolation, and fitted with a modified exponential derived from gradient mapping experiments as described in Section 3.1.

Overall, the distribution of signals in the diffusion domain of spectrum of Figure 4 is dominated as expected by the

Figure 5 400 MHz ^1H - ^{13}C DOSY-HMQC data for the same mixture as Figure 4, with (left) the integral projection of the 3D spectrum onto the diffusion axis, and (right, from top) integral projections onto the ^1H - ^{13}C plane for the diffusion regions 5.9–6.9 $\times 10^{-10}$ (quinine, Q), 9.0–10.0 $\times 10^{-10}$ (geraniol, G), and 12.1–13.1 $\times 10^{-10}$ m² s⁻¹ (camphene, C)

diffusion coefficients of the four main species present, quinine, geraniol, camphene and TMS. These appear as four strong distinct peaks in the integral projection of the spectrum onto the diffusion axis, shown at the left. Above 2 ppm, all of the signals appear at the expected positions in the diffusion domain, with one exception. At 4.9 ppm the quinine multiplet lies on top of the broader residual water signal, with the result that the apparent diffusion coefficients of the quinine signals are increased and that of the water slightly decreased. This effect can be reduced but not eliminated by the use of resolution enhancement to reduce the overlap between the signals; however, the shifts in the signals are simple, predictable and easily accounted for, and do little to damage the interpretability of the spectrum. Below 2 ppm the large number of aliphatic proton signals from the three main species gives rise to more severe overlap, with the result that a significant number of signals are displaced to lie at averaged apparent diffusion coefficients. As the diffusion projection shows, 95% of the overall signal intensity remains at the correct diffusion coefficient; in this sample only low intensity signals show significant deviations from their expected positions, although the difficulty of reproducing contour plots for spectra with such high chemical shift resolution exaggerates their apparent importance.

Where sensitivity considerations permit, 3D DOSY methods offer a large improvement in resolution. Figure 5 shows data from a 3D DOSY-HMQC (heteronuclear multiple quantum coherence) experiment¹⁹ on a similar sample of quinine, geraniol and camphene. Five diffusion-weighted HMQC datasets of 512×1024 complex data points were acquired in a total time of 17 h, with a diffusion time of 45 ms and pulse gradient strengths from 1 to 30 G cm^{-1} . Peak volumes were determined for all cross peaks and fitted to a simple exponential as a function of q^2 . The extra resolution afforded by separating signals according to both ^1H and ^{13}C chemical shifts now ensures that all signals, including those for the aliphatic protons, are well-resolved. Thus while the relative accuracy with which diffusion coefficients are determined is reduced compared to Figure 4 because of the small number of different gradient strengths used, the 3D experiment nevertheless successfully resolves all the signals in the mixture.

1 INTRODUCTION

Pulsed magnetic field gradients can be used in NMR to suppress unwanted magnetization, or to encode space, motion, and coherence order. These applications, which are central elements of in vivo magnetic resonance, can also be used to enhance high-resolution NMR spectroscopy. There are several ways in which a conventional NMR experiment can benefit from pulsed field gradients. Coherence pathway selection using field gradient pulses instead of phase cycling can minimize data collection time, reduce artifacts, and avoid signal loss associated with traditional water elimination methods. Differences in the rates of molecular motion between solvent and macromolecules can be exploited to achieve linewidth and lineshape independent water suppression. The consequences of poor homogeneity can be reduced using spatially selective excitation, and spoiler gradients can be used to selectively eliminate unwanted magnetization. The present article describes the development and application of B_0 pulse field gradients in high resolution NMR spectroscopy. For a description of B_1 gradient applications see *Radiofrequency Gradient Pulses*.

2 EARLY APPLICATIONS

The first report of using pulsed field gradients was published in 1955 and described the potential of magnetic resonance for information storage.¹ This work detailed the use of gradient pulses in multipulse, multiecho NMR to eliminate selectively unwanted signal. In this paper, bracketing a 180° refocusing pulse with a symmetric gradient pair was introduced as an efficient way to avoid spurious echoes. Further, the application of a gradient pulse during a z axis storage interval was introduced as a way to select for stimulated echoes. These early

pulsed gradient applications are still used in contemporary NMR, especially in imaging and localized spectroscopy, where they have taken on names such as primer–crusher pairs, crushers, and spoiler gradients. These concepts are also important for the application of pulsed gradients in high-resolution NMR spectroscopy.

The use of pulsed field gradients to measure molecular diffusion was introduced in 1965 by Stejskal and Tanner.² This approach overcame severe bandwidth limitations associated with earlier static gradient measurements. In this method, transverse magnetization is encoded with spatially dependent phase by application of an initial gradient pulse, allowed to stay encoded for a fixed period of time, and then rephased by a second gradient pulse. The loss of recoverable signal due to the movement of spins is related to the diffusion coefficient by the Stejskal–Tanner equation:

$$\ln(S/S_0) = -\gamma^2 g^2 \tau^2 (\Delta - 1/3\tau) D \quad (1)$$

where γ is the magnetogyric ratio, g is the strength and τ the duration of the gradient pulse pair, Δ is the time between gradient pulses, and D is the diffusion coefficient (see also *Diffusion Measurements by Magnetic Field Gradient Methods*). The large difference in D for macromolecules relative to solvent water provides the basis for the use of diffusion gradients in spectroscopy.

In 1968, Vold and co-workers³ used a spoiler gradient to overcome imperfect 180° inversion in a T_1 recovery sequence. Shortly thereafter, the benefits of using spoiler gradients, or homospoil pulses, as they sometimes became to be known, were reported by a number of groups. One of the best known applications has been as a mix time spoiler in the NOESY experiment (see also *NOESY*).

Even spatial resolution has shown potential value in high-resolution spectroscopy. As will be discussed later in this article, slice selection can be used to reduce end effects from sample and coil, and field maps may provide a way to optimize homogeneity. For a description of the development of spatial applications of pulsed field gradients see *Magnetic Resonance Imaging: A Historical Overview*.

In 1977, Wokaun and Ernst⁴ described the relationship between coherence order and the effect of a gradient pulse. The idea of using gradients for coherence pathway selection was further developed by the studies of several groups.^{5–8}

3 GRADIENT HARDWARE CONSIDERATIONS

3.1 Eddy Current Compensation

In early studies, potential benefits of using pulsed gradients were often overshadowed by drawbacks such as long gradient recovery times, increased phase instability, peak shape distortion, and, for high-resolution applications, disturbance of the field/frequency lock system. The problem is with the induced eddy currents generated in conductive materials by the switched gradient field. This may include such items as the magnet cryoshields, the bore tube, and the coil itself. The transient fields generated by eddy currents have a variety of decay times which may be of the order of milliseconds, or can persist for seconds. To reduce this problem, the gradient

amplifier can be overdriven to compensate for these undesirable fields. This approach, referred to as preemphasis, is in common use on almost all modern gradient systems, but does not completely overcome the problem (*Eddy Currents and Their Control*).

3.2 Gradient Amplifier Noise

With the incorporation of strong ($>200 \text{ mT m}^{-1}$) pulsed gradient systems into the NMR experiment, it is important to consider the dynamic range of the gradient amplifier. For example, a 1 T m^{-1} gradient is capable of producing $425\,800\,2\pi \text{ radians s}^{-1}$ gradient across a 1 cm sample. The tolerance of most experiments requires that any variation of the amplifier quiescent state (the noise floor) be significantly less than 10^{-7} of this peak value. For many experiments, especially those in which a nonrectangular gradient wave form is used, 16-bit control of the gradient amplitude is also desirable.

3.3 Actively Shielded Gradients

One of the most important improvements in gradient technology for NMR has been the introduction of actively shielded gradients (see *Gradient Coil Systems*). The basic idea is to provide a second coil of opposite polarity outside the primary gradient coil, which is then driven to buck the stray field generated outside the primary coil. In practice the combination of active shielding and preemphasis gives the best performance.

Phase error can also come from movement of the coil during sharp gradient transitions. This is the source of the characteristic sound made by gradient pulses, sometimes referred to as the speaker-coil effect. It is often desirable to attenuate the amplitude and ring down time of this vibration. Reduced mechanical noise from the gradients is usually accomplished by potting the coils in a nonconductive material such as concrete or epoxy. These coils must also be designed to dissipate the significant heat that can be generated by gradient experiments.

3.4 Single-Axis versus Three-Axis Gradients

In any experiment which consists of multiple rf and multiple gradient pulses, care must be taken to avoid recovering unwanted signal dephased earlier in the pulse sequence. This is relatively straightforward, and can be achieved by prudent choice of sign, amplitudes, or durations of the gradient pulses. If multiple axes are available, gradient cycling has been shown to be effective.⁹ In practice, single z axis gradient coils have been more widely available for high-resolution applications, and have proven sufficient to provide improvements over conventional phase cycled methods. Unfortunately, in some cases the static gradients generated by the homogeneity shims can create a problem. Although weak in comparison to the applied gradient pulses, these static gradients may have over 1 s (e.g. acquisition time) to rephase the effect of a 1 ms or shorter gradient interval.

In 1971, Redfield and Gupta¹⁰ commented on the formation of unwanted gradient echoes when using spoiler gradients. The

misadjustment of shims, in the same direction as the applied gradient, is suggested as a way to prevent this accidental rephasing by the static shim gradients during acquisition. Misadjustment of shims, however, is rarely desirable. Further, in the case of high order z shims, the rephased signal may be from a small part of the NMR sample. An effective approach to reducing this problem is to avoid application of a pure z pulsed gradient, using additional x and/or y gradients to provide an off z axis distribution of phase.¹¹

3.5 Sample Spinning and Field Frequency Locking

Although the effect of a gradient pulse on a deuterium field/frequency lock system is reduced relative to protons by γ_D/γ_H , lock blanking during the gradient pulse can be valuable. Recovery of the steady-state lock signal is determined primarily by the sensitivity of the lock as reflected in the M_{xy}/M_z of the deuterium spins, and by the T_2 relaxation rates of the deuterium solvent. Lock recovery rates can be very favorable for strong lock solvents such as the 5–10% D_2O commonly used for biochemical studies.

Sample spinning is only compatible with z axis gradient application, and even there care must be taken to avoid vortexing of the sample. Any increased mixing leads to signal loss in both diffusion weighted and in gradient coherence selection methods. Also, in practice, sample spinning has been observed to reintroduce t_1 noise, partially negating one of the benefits of using gradients in the first place. Fortunately, full performance can be achieved nonspin for most biochemical samples.

4 THE EFFECT OF MAGNETIC FIELD GRADIENTS

4.1 Dephasing

The application of a pulsed field gradient generates a reversible distribution of phase

$$\phi_r = \gamma(g\tau)rp \quad (2)$$

where γ is the magnetogyric ratio, g is the gradient strength, τ is the gradient duration, r is the distance from gradient isocenter, and p is the coherence order. This effect can be visualized by mapping the effect of gradient pulse on a phase sensitive proton image as shown in Figure 1. As expected the application of a rectangular, 10 mT m^{-1} gradient of 1 ms in duration generates approximately three 2π cycles of phase along the z axis of a 1.5 cm long water sample. If not resolved in space, the signal from the volume of spins self-cancels. The effectiveness of cancellation increases with gradient integral $g\tau$.

The amount of gradient needed for complete signal dephasing is variable and depends strongly on factors such as B_1 homogeneity and bulk magnetic susceptibility shifts. Although these would appear to be well controlled in a typical high-resolution NMR experiment, small deviations can make a significant difference when the amount of unwanted signal is large, as it is for most dilute biochemical samples in 90–95% H_2O . The largest variations in B_1 are in the transition bands, at the ends of the rf coil, where B_1 goes from maximum to zero. Short samples and bubbles can lead to localized frequency shifts, which also lead to inefficiency in self-cancellation.

Figure 1 Phase sensitive image of a water sample in a standard 5 mm NMR tube. The effect of a 1 ms 10 mT m^{-1} rectangular z gradient pulse is recorded. The height of the detected volume is about 1.5 cm. As illustrated by the image and accompanying profile, the expected phase distribution is encoded by the applied gradient pulse. The curvature at the ends of the sample is the fall-off of x gradient strength as a function of z

5 COHERENCE PATHWAY SELECTION

Coherence selection using gradients takes advantage of the field dependence of coherence order. This dependence is described in terms of the phase generated by an applied gradient as shown in equation (2). In its simplest form, a sequence of rf pulses and delays generate multiple coherence pathways. A particular pathway can be selected, for example, by application of a gradient pulse to coherence order label the spins during an evolution or mixing delay interval, followed by the application of a read gradient just prior to data acquisition to rephase the desired pathway. This assumes that the chosen pathway will have zero net phase gradient and that the unwanted pathways will have a net distribution of phase, and therefore self-cancel. In general, signal will only be observed from pathways in which

$$\sum_i G_i p_i = 0 \quad (3)$$

where G_i represents the integral ($g\tau$, for a rectangular gradient pulse) of each gradient interval, i , and p_i is the coherence order during each interval, i .

5.1 Density Operator Description

The effect of a pulsed magnetic field gradient on the nuclear spin can be understood by describing the state of the spin system in terms of density operators. Many different formalisms express the density operator in matrix elements of appropriate sets of operators in a Cartesian or spherical basis.

A detailed description of the effect of magnetic field gradients on the magnetization or coherence component is given by Counsell et al.⁸

For the purpose of describing the effects of magnetic field gradients, it is convenient to classify the density operator $\rho(t)$ of the spin system at any time t according to its various coherence orders or components:

$$\rho(t) = \sum_p \rho^p(t) \quad (4)$$

where p and ρ^p represent a particular coherence order and the density operator component corresponding to that coherence order. The spin coherences undergo precession during a gradient pulse, and the extent of precession depends on the spatial coordinate r of the spin, and the coherence order p of that particular component. Hence the Hamiltonian of the spin system during the gradient pulse is predominantly from Zeeman contributions. The Zeeman fields experienced by the various spins in the sample vary according to their spatial coordinates. The precession or rotation can be represented by $\exp\{-i\omega_z(r)F_z\tau\}$, where $\omega_z(r)$ is the precession frequency at a spatial position r , and τ is the duration of the field gradient pulse, and F_z is the z component of the total angular momentum. Classification of the density operator into the various coherence order components is convenient, since the effect of the field gradient pulse can be written as

$$\rho^p(t-) \xrightarrow{\exp\{i\omega_z(r)F_z\tau\}} \exp\{-ip\omega_z(r)\tau\}\rho^p(t+) \quad (5)$$

which describes the transformation of the p th component of the density operator ρ . $\rho(t-)$ and $\rho(t+)$ are used to label the density operator before and after the gradient pulse. As the right hand side shows, the effect of the gradient pulse is to modulate the density operator component by a complex phase factor. This phase factor depends on the coherence order of the component and on the integral of the gradient pulse. In other words, the phase of each magnetization component is modified by a factor which depends on the coherence order of the component, spatial position of that particular spin and also on the duration and amplitude of the applied field gradient. If we consider heteronuclear spins, the phase factor would also take into account the magnetogyric ratio of the nuclear spin. Essentially, the effect of the gradient pulse is to defocus the coherence by a controlled amount. Each of the coherence pathways can be thought to be coherence order labeled by the gradient pulse. Selection of a particular pathway or decoding is then accomplished by applying a rephasing gradient pulse with amplitude and duration $\omega_z^R(r)\tau^R$, which transforms the density operator described by

$$\sum_k C_k \rho^{(-1)} \exp\{-i\phi_k\} \quad (6)$$

where k is the index for a particular coherence pathway in the experiment, ϕ_k is the cumulative phase dispersal for that particular pathway, C_k denotes all of the time dependence and $\rho^{(-1)}$ denotes the observable component of the density operator, corresponding to coherence order $p = -1$. This can

4 FIELD GRADIENTS AND THEIR APPLICATION

be written as

$$\sum_k C_k \rho^{(-1)} \xrightarrow{\exp\{-i\omega_z^R(r)F_z\tau^R\}} C_1 \rho^{(-1)} + \sum_{k \neq 1} C_k \rho^{(-1)} \exp\{-i(\phi_k + \omega_z^R(r)\tau^R)\} \quad (7)$$

where 1 denotes the desired coherence pathway in the experiment. The first term on the right hand side $k = 1$, corresponds to the pathway which has been exactly decoded, and hence observed since

$$\phi_k = -\omega_z^R(r)\tau^R \quad (8)$$

The second term denotes all the other pathways which are still defocused and are not observable. Equation (5) describes the most important feature of all coherence transfer selection schemes, including rf phase cycling, B_0 and B_1 gradient methods. In conventional rf phase cycling methods, each coherence component accumulates phase factors during the various cycles of the phase cycle. The receiver phase cycle is then determined such that only the desired pathways yield a signal (see also **Phase Cycling**). In the case of pulsed field gradients, each of the gradient pulses contributes to the cumulative phase factors of the various coherence components. The desired pathway is then selected by choosing the appropriate rephasing gradient integral (the product of amplitude and duration for rectangular gradient pulses) prior to data acquisition. A major feature of gradient selection of coherence pathways is that the selection is accomplished in a single acquisition, unlike rf phase cycling, where multiple acquisitions are required. It can be thought of as phase cycling in space rather than time. Also, the major limitation of gradient pathway selection has been the loss of all but a single pathway, resulting in lower sensitivity.

5.2 Coherence Pathway Diagrams

Coherence pathway diagrams^{12,13} are a convenient way to visualize the use of gradients. This is illustrated with the homonuclear correlation experiment, COSY, in Figure 2. The spin system starts at thermal equilibrium with $p = 0$ and is detected in quadrature with $p = -1$. For this rf sequence there are two coherence pathways, $p = (0, -1, -1)$ and $p = (0, +1, -1)$. According to equation (3), a pathway will be selected only if $p_1 G_1 + p_2 G_2 = 0$. For the first pathway, where p_1 and p_2 are of the same sign, the gradient integral G_2 must be the negative of G_1 . For the second pathway, where $p_2 = -p_1$, G_1 and G_2 must be identical. In a similar way, a pair of identical gradient pulses eliminates spurious signals in a spin echo experiment by selecting for a sign change in coherence order (e.g. $p = +1$ to -1 and $p = -1$ to $+1$). Unwanted signal excited by an imperfect 180° pulse will be dephased, $p_2 G_2 \neq 0$.

For the multiple quantum experiments a third rf pulse adds another coherence transfer interval, and adds the possibility of using DQ coherence levels $p = \pm 2$. For the double quantum filtered correlations (DQF) COSY sequence illustrated in Figure 3, a gradient ratio, $G_1:G_2:G_3$ of 1:1:3, selects for one of the four DQ coherence pathways $(0, +1, +2, -1)$.

Figure 2 Pulse sequence and coherence pathway diagrams for the incorporation of pulse field gradients in COSY. P type $(0, -1, -1)$ COSY is selected when $G_2 = G_1$ and N type $(0, +1, -1)$ is selected when $G_2 = -G_1$

6 HOMONUCLEAR APPLICATIONS

For small organic molecule NMR, the major use of pulse field gradients is speed and reduction of artifacts in simple 2D NMR. For aqueous based proton NMR, gradient selection of multiple quantum pathways to discriminate against water, is an important application.

The uncoupled spins of water cannot generate $p = \pm 2$ coherence order, and can easily be left dephased during the detection period. This has been an advantage for in

Figure 4 Noise floor contour plot of 400 MHz GE DQF COSY spectrum of 8 mM angiotensin II in H₂O. An 800-fold vertical expansion of the reference one-pulse spectrum is shown above the contour plot. 2D data were collected at 4 Hz resolution in ω_1 and ω_2 without phase cycling. A transmitter zero-frequency artifact, not residual water, is responsible for the intensity at 4.6 ppm. (Adapted by permission of Academic Press from Hurd¹⁵)

vivo detection of lactate.¹⁴ The single-shot selection process avoids the motion related subtraction errors that can be a problem in vivo. The further addition of rf selective coherence transfer provides extraordinary discrimination between the lactate methyl signal and the overlapping lipid CH₂ in a 2D DQ sequence.¹¹ Success of the in vivo results obtained using actively shielded gradients led to experiments with this technology on high-resolution NMR systems. Not surprisingly, one of the first experiments was gradient enhanced GE DQF COSY.¹⁵ As illustrated by the noise floor contour plot shown in Figure 4, this approach to solvent suppression does not perturb signals close to or at the water chemical shift. It is also apparent that the nonsubtractive nature of gradient coherence pathway selection reduces the problem of t_1 noise.

7 PROTON DETECTED HETERONUCLEAR APPLICATIONS

7.1 GE HMQC

Proton detection of low γ nuclei is a good example of a method in which the desired signal is but a small part of the overall proton magnetization. As such, this type of experiment lends itself well to the application of gradients. The pulse sequence and modified coherence pathway diagram for a gradient enhanced version of a heteronuclear correlation experiment GE HMQC¹⁶ are shown in Figure 5. In this diagram, shared coherence levels are drawn using a γ_H normalized coherence order

$$p' = p(^1\text{H}) + p(\text{X})\gamma_X/\gamma_H \quad (9)$$

Since phase distribution is proportional to the product of p' and gradient integral G , signal will only be observed for transverse magnetization from pathways for which the sum of the effects from all of the individual gradient pulses goes to zero:

$$\sum p'[i]G[i] = 0 \quad (10)$$

For $^1\text{H}/^{13}\text{C}$ experiments, $\gamma_X/\gamma_H = 0.25$. This means, for example, that $^1\text{H}[+1]^{13}\text{C}[-1]$ zero-quantum coherence will have a normalized order $p' = 0.75$. A gradient, G_1 , applied during such an interval will cause a coherence pathway through this zero quantum level to be encoded with a distribution of phase, $\phi = 0.75G_1$. To select for this pathway, a read ($p' = -1$) gradient, G_3 must be set to $0.75G_1$. This pathway, $\text{H}[0]\text{C}[0] \rightarrow \text{H}[+1]\text{C}[0] \rightarrow \text{H}[+1]\text{C}[-1] \rightarrow \text{H}[-1]\text{C}[-1] \rightarrow \text{H}[-1]$, can also be selected using alternate ratios of gradients $G_1:G_2:G_3$. These sequences can be optimized for best use of available gradient strength for dephasing (2:2:1) or can be optimized to avoid certain artifacts.¹⁷

In natural-abundance carbon experiments, more than 99% of the signal must be subtracted out to reveal the protons attached to the 1% abundant ^{13}C nuclei. With gradient selection, protons attached to ^{12}C and from solvents such as water are not detected, thus avoiding subtraction and dynamic range limitations. The effectiveness of this suppression is illustrated in Figure 6 by a noise floor contour plot of a single acquisition

Figure 5 Pulse sequence and coherence pathway diagram for GE HMQC

per block $^1\text{H}[\text{natural abundance } ^{13}\text{C}]$ GE HMQC spectrum of sucrose in water. In this example, without broadband ^{13}C decoupling, the correlations are observed as ^{13}CH doublets. The absence of signal at the ^{12}C proton chemical shifts and at the water chemical shift in this spectrum demonstrate the complete cancellation of signal from protons not attached to ^{13}C . Another good application is in the long range heteronuclear multiple bond correlation (HMBC) experiment where t_1 noise from the uncoupled protons may obscure weak long range $^{13}\text{C}-^1\text{H}$ correlations in a conventional experiment.

7.2 3D and 4D Applications

It was recognized from early on that the reduction in the phase cycle requirement and the concomitant reduction in total data collection time would be a significant reason to use pulse field gradients in 3D and 4D applications. These experiments usually require large numbers of acquisitions just to achieve adequate resolution in the evolution domains. In fact, in some cases, it is the phase cycle and not the signal-to-noise ratio (S/N) which dictates the length of data collection time. A number of multidimensional methods have been developed to take advantage of the reduced data collection time, water suppression characteristics, and fewer artifacts.^{18–23} Others have taken advantage of reduced phase cycle to increase resolution in the evolution dimensions.²⁴

One of the first 3D gradient sequences was a modification of HMQC-COSY. The GE HMQC-COSY sequence¹⁸ is a combination of a gradient-enhanced HMQC experiment, in which heteronuclear zero quantum magnetization is coherence order labeled and then selectively rephased via a 4:–3 gradient pair surrounding the final carbon 90° pulse, and a gradient-enhanced COSY experiment in which quadrature in the COSY dimension is selected with a 1:1 gradient pair around the final 90° pulse. The resulting gradient integrals are 4:–2:1. The asymmetry of this gradient pulse scheme leaves protons which are not at least indirectly connected to ^{13}C dephased and unobserved. This method provides editing, simple pattern

Figure 6 Noise floor contour plot of a 2 min total acquisition time $^1\text{H}[^{13}\text{C}$ natural abundance] GE HMQC spectrum of sucrose in water shows complete elimination of ^{12}C protons and solvent water

Figure 7 C-6 plane from a $512 \times 128 \times 128$ GE HMQC-COSY spectrum of menthol collected in less than 7 h. Simple correlation patterns are observed for direct and remotely coupled protons. (Reproduced by permission of Academic Press from Hurd and John¹⁸)

recognition features, and in some cases additional resolution. Without the need for phase cycling, a moderate resolution $512 \times 128 \times 128$ spectrum can be obtained in just a few hours. As illustrated by the C-6 plane of menthol, shown in Figure 7, protons directly attached to carbon are observed as $J(\text{C,H})$ doublets along the $\omega_3 = \omega_2$ diagonal. A proton attached to a directly adjacent carbon (^{12}C) is observed at its ^{12}C proton chemical shift in ω_3 , and at the frequencies of the directly (^{13}C) attached proton in ω_2 (see, for example, the H-6b,H-1 correlation). Proton connectivities from two carbon bonds away are observed as single correlations at the ^{12}C proton chemical shift in ω_3 and at the ^{12}C proton chemical shift of the intermediary proton in ω_2 (see, for example, H-6,H-10). The inequivalent CH_2 protons of C-6 (H-a,H-b and H-b,H-a correlations) remain coupled in both ω_2 and ω_3 to give a parallel squares pattern. This occurs because both protons are attached to the same ^{13}C nuclei.

Proton detected 3D SQ-DQ COSY of ^{13}C enriched sugars has been reported to be more useful with the incorporation of pulse field gradients, yielding ‘unsurpassed’ resolution plus better overall artifact suppression.²⁴

7.3 Protein NMR Applications

The analysis of protein structure by NMR has been a driving force in the development of proton-detected multidimensional methods. The success of these applications often depends on the ability to identify, assign, and obtain distance information from C- α ,H resonances. The proximity of these signals to the water chemical shift can be a problem in some cases. Traditional methods of water suppression often exhibit an inherent disadvantage. Selective excitation often results in the loss or attenuation of desired signals near the water resonance and, when presaturation is used, magnetization transfer and proton exchange can lead to a loss of signal intensity throughout the spectrum. Although these issues can be managed, in part, by compromises in solvent conditions and temperature, gradient based coherence selection offers an alternative. GE HMQC-TOCSY and GE HMQC-NOESY give full unobscured C- α ,H correlations at water chemical shift.¹⁹ These experiments were also among the first gradient coherence selection experiments run using a field/frequency lock and variable temperature; these are key requirements for routine use of gradients.

8 WATER ELIMINATION

Removal of the large unwanted water signal without perturbing the desired signal has been one of the great technical challenges of biomolecular proton NMR. Potential difficulties include exchangeable protons, a crowded water chemical shift region, and correlation times which allow signal loss via magnetization transfer. Gradients have had an increasingly important role in this area. The advantage relative to presaturation has been quantitatively measured using gradient versions of the heteronuclear single quantum correlation (HSQC) experiment.^{25,26} As illustrated in Figure 8, the retention of signal is most significant for proteins in the physiologically important pH range of 6.5–7.5.²⁶ Elimination of the presaturation effect reveals the smaller loss of signal due to a ‘short’ recycle delay. This second effect is presumably due to an increased rate of exchange with long T_1 water protons at higher pH. In addition to multiple quantum coherence pathway selection, there are several other gradient based methods which can be used for water suppression. Spoiler gradients can be used in combination with selective rf excitation as an effective replacement of conventional presaturation, gradient pairs can be used to improve selective spin echo methods, and diffusion weighted methods can provide lineshape independent water reduction (*Water Signal Suppression in NMR of Biomolecules*).

8.1 CHESS

In a method sometimes referred to as a *chemical shift selective* (CHESS)²⁷ pulse, water is selectively excited and

Figure 8 1D ^{15}N - ^1H PFG HSQC spectra showing saturation transfer between solvent H_2O and the ^{15}N -labeled amide protons of 0.8 mM Ac-L-Asn-L-Pro-L- ^{15}N Tyr-NHMe at various pH values and a temperature of 30 °C. (A) PGF HSQC spectra recorded with 1.3 s of water presaturation and total recycle time of 3.3 s. (B) PFG HSQC spectra recorded without presaturation and with a total recycle time of 3.3 s. (C) PFG HSQC spectra recorded without presaturation and with a total recycle time of 15.3 s. (Reproduced by permission of Academic Press from Li and Montelione²⁶)

then spoiled by application of a pulsed field gradient. For optimum elimination the tip angle of the excitation pulse must be adjusted for water T_1 relaxation which occurs during the excitation-dephase intervals. For high-resolution applications, this delay period can be increased to allow for recovery of shorter T_1 signals of interest at the water chemical shift.²⁸ When used for in vivo applications, where the volume of interest usually has multiple water T_1 values, a series of intervals (usually three) is used to provide the optimum water elimination. In practice, multiple CHESS pulses also improve water elimination in high-resolution NMR applications. This is likely due to B_1 rather than T_1 heterogeneity. In the case of multiple CHESS pulses, care must be taken to avoid the rephasing of water. This can be accomplished by using spoiler gradients with different intensities, durations, or axes. This method is not only dependent on gradient performance, but also on selective rf pulse design. Desirable features of these rf pulses are minimum out-of-band excitation and sharp transition bands. Since the water signal is to be dephased anyway, the phase in the excitation band is unimportant and can be sacrificed in pulse design.²⁸

8.2 Spin Echoes and Gradient Pairs

Elimination of the unwanted signals generated by the non- π character of selective time reversal pulses is an important application of pulse field gradients. A pair of gradients placed on either side of a 180° pulse to avoid spurious signal, one of the first applications of pulse field gradients, can provide significant improvement in modern high-resolution NMR. Placed on either side of a nonselective 180° refocusing pulse, a gradient pair eliminates unwanted signal from imperfections in B_1 that would ordinarily have to be eliminated by phase cycling. This effect can be even more dramatic with frequency selective π pulse methods. Figure 9 illustrates the benefit of a gradient pair in the performance of gradient enhanced spin echo water suppression (GE SEWS), a selective 1-1 spin echo experiment.

8.2.1 WATERGATE

In a related experiment dubbed WATERGATE,²⁹ water suppression by gradient-tailored excitation is also accomplished using a gradient pair to improve a frequency selective spin echo. In this case, the frequency selectivity is achieved using a nonselective 180° pulse/water selective $180^\circ(-x)$ pulse combination. This has the advantage that peaks away from the water signal see only a nonselective spin echo. The disadvantage of these frequency selective methods is that they give up the chemical shift region near water.

8.3 Diffusion Weighted Water Suppression

The difference between the translational diffusion of a large solute molecule such as a protein and that of solvent water is the basis of the DRYCLEAN water suppression method.³⁰ DRYCLEAN comes from *diffusion-reduced* water signals in spectroscopy of molecules moving *slower than* water. The idea is that water will move far enough in the time between the encode and the decode gradient pulses to remain dephased, while the large solute molecule will not move very far and will be largely rephased. According to equation (1), for a modest 20-fold difference in diffusion constant, D , a gradient pair could be selected to preserve over 70% of solute signal, while suppressing water by 1000-fold.

9 PHASE SENSITIVE METHODS

Modern multidimensional spectra are almost always recorded in pure absorption mode. The primary reasons are improved resolution and lineshape, and an increase of root-2 (about 40%) in S/N compared with magnitude mode. Absorption mode spectra are also phase sensitive.

Typically, pure absorption phase is obtained by amplitude modulation of the signal as a function of the evolution period t_1 , in contrast to phase modulation in the magnitude methods. Amplitude modulation yields separable phases (separable to absorption and dispersion), but loses the ability to discriminate between positive and negative frequencies. Frequency discrimination can be obtained by independent collection of the real and imaginary parts in t_1 (quadrature

Figure 9 GE SEWS: comparison of spin echo water suppression (a, c) without and (b, d) with a gradient pair bracketing the semiselective 1–1 refocusing pulse. Suppression is shown for the 90% H₂O in a 2.6 mM sample of ¹⁵N-enriched bovine pancreas trypsin inhibitor (BPTI). A single acquisition without gradient pair shown in (a) reduces water only by a factor of 50 and thereby limits optimization of receiver gain and ultimate SNR. In (b) complete suppression is obtained in a single acquisition using the gradient method allowing optimum setting of receiver gain. Although phase cycling improves the water suppression in the method without gradients (c), neither suppression or S/N matches the level achieved using the gradient pair (d). (Reproduced by permission of GE NMR Instruments)

data in t_1). Complex Fourier transformation of these data in t_1 produces spectra with quadrature detection in ω_1 . By acquiring mirror image pathways (+1) and (–1) in t_1 , this approach provides pure absorption shapes for the correlation peaks, and quadrature detection in the evolution dimension(s).

In the case of phase sensitive detection in gradient spectroscopy, there can exist a fundamental limitation. The single-shot selection of a unique coherence pathway precludes the acquisition of the mirror image pathways of (+1) and (–1). If both pathways are not acquired, mixed phase (absorption and dispersion components mixed in an inseparable manner) results for the correlation peaks. Hence the earlier gradient spectroscopy experiments were carried out in the magnitude mode. The requirement for selection of mirror image pathways for pure absorption mode can be at odds with that for improved dynamic range performance which requires selection of a unique pathway in a single acquisition.

The methods developed for pure absorption spectra in gradient spectroscopy adopted a compromise approach. The

techniques can be broadly classed as: (a) those which acquire both the mirror image coherence pathways simultaneously by not applying a field gradient during the evolution dimension, albeit, using gradients elsewhere in the pulse sequence; (b) those which acquire both mirror image coherence pathways (+1) and (–1) in the evolution dimension, independently, and then combine both of these signal components in the time domain or in the frequency domain, to yield pure absorption spectra; (c) methods which use gradients as spoilers only and not for coherence pathway selection; and (d) methods which switch between the signals from the two mirror image pathways during the acquisition time.

9.1 Phase Sensitive GE DQF COSY

The DQF COSY experiment proposed by Davis et al.³¹ falls into category (a). In this experiment, gradients are used to select DQ coherence transfer. However, gradients are not

Figure 10 Pulse sequence and coherence pathway diagram for phase sensitive GE DQF COSY as described by Davis and co-workers³¹

applied during the evolution period. With this modification, both mirror image coherence pathways are allowed during t_1 and pure absorption lineshapes can be obtained in the 2D spectrum. This work also addresses the problem of time dependent phase errors associated with chemical shift precession during the gradient pulse. In this pulse sequence as shown in Figure 10, these phase errors are refocused by the addition of a 180° rf pulse. The DQ selection is made using a pair of gradients G_1 and G_2 about the read pulse with a ratio of 1:2. The gradient sequence selects two of the four possible DQ pathways and hence the S/N of the experiments is root-2 (40%) lower than that of conventional phase cycled DQF COSY. Some of the loss can be avoided by use of an optimized tip angle for the read pulse. Frequency discrimination in t_1 is obtained in the normal manner.

The addition of a CHESS pulse (water selective excitation–gradient dephase interval), as described in the previous section, allows reduced gradient coherence selection intervals, and makes this an attractive approach for the study of biomolecules in water.

9.2 Phase Sensitive GE HMQC and GE HSQC

There are a variety of methods which belong in category (b), where the mirror image components corresponding to (+1) and (−1) coherence orders are acquired separately and then recombined in the time or frequency domain. Most of the proposed methods for gradient enhanced proton detected heteronuclear correlation^{32–36} fall into this category. One example is the phase sensitive ^1H – ^{13}C HMQC experiment described by Tolman et al.³³ The sequence consists of a HMQC sequence with three gradients G_1 , G_2 , and G_3 , as shown in Figure 11. G_1 and G_2 are applied during the multiple quantum period on either side of the central proton 180° . Additional 180° pulses on both ^1H and ^{13}C are applied to refocus chemical shift precession that has occurred during the gradient intervals. The final gradient G_3 is applied after the last ^{13}C 90° . The sign of the final gradient is changed to retrieve the mirror image pathway. These two pathways correspond to mirror images in t_1 , and are collected separately and subtracted to produce the real part of t_1 and are added to produce the imaginary part of

Figure 11 Pulse sequence and modified coherence pathway diagram for phase sensitive pulse field gradient HMQC described by Tolman et al.³³

Figure 12 Phase sensitive ^{15}N – ^1H GE HMQC spectrum of 100 μM ketosteroid isomerase (KSI) (27 kDa dimer) in 90% H_2O at 37°C obtained at 500 MHz. (Sample provided by courtesy of M. Summers, University of Maryland)

t_1 . Ross et al.³⁶ avoid the use of additional refocusing pulses by back-prediction of the t_1 domain. The method described by Tolman et al.³³ was used to collect the phase sensitive GE HMQC spectrum of the dilute (100 μM in 90% H_2O) protein sample shown in Figure 12. Here again, the addition of a CHESS pulse interval allows the use of shorter coherence selection intervals and allows for the study of larger, more dilute molecules. The unmatched level of water suppression is characteristic of the coherence selective B_0 gradient methods.

9.3 Heteronuclear zz Filters

The most compelling benefit arising from the use of gradient coherence pathway selection in proton detected heteronuclear correlation experiments is the nearly complete elimination of signal from protons not attached to the

heteronuclear spins. This advantage is especially important for the suppression of water protons since conventional methods such as presaturation and most of the selective excitation methods can lead to loss of desired signal. Unfortunately, some of the benefits of these experiments are offset by the loss of a factor of root-2 in the S/N that results from the selection of a single or limited number of coherence pathways. On the other hand, the suppression of protons not attached to the X nucleus, and of the solvent proton resonance, can be a challenging task in the conventional, phase cycled methods. One approach to reduce this problem, which belongs in category (c) above, was described by Brühwiler and Wagner.³⁷ This approach takes advantage of the heteronuclear longitudinal spin order (described by the density operator $I_z S_z$, and also termed heteronuclear zz magnetization) which is formed by the sequence fragment $90_x(^1\text{H})-\tau-180_x(^1\text{H}, \text{X})-\tau-90_y(^1\text{H})$ where τ is $1/4J(\text{X}, \text{H})$. In this method, referred to here as the heteronuclear zz filter, protons not attached to the X spins remain in the transverse plane following this interval and are eliminated by application of a spoiler gradient. Although this method maintains full sensitivity, it is not overly effective at eliminating magnetization from protons that are not attached to the X nucleus, and especially those for H_2O solvent.

This approach has been successfully applied in combination with other suppression schemes.^{38–43} The symmetry of the HSQC sequence allows for incorporation of two zz filters.⁴⁰ This approach maintains full sensitivity and pure absorption peak shapes, since all the necessary coherence pathways are selected. A HSQC sequence with gradient zz filters is shown in Figure 13. The gradient G_3 dephases the transverse magnetization while the desired components are stored along the z axis. As in the conventional HSQC experiment, X chemical shift labeling occurs in the evolution time, t_1 , between the two $90^\circ(\text{X})$ pulses, and the application of the $180^\circ(^1\text{H})$ pulse in the center of the evolution time removes the $J(\text{X}, \text{H})$ coupling from the evolution dimension. The frequency labeled magnetization is transferred back into heteronuclear longitudinal zz order by the second $90^\circ(\text{X})$ pulse, and the spoiler gradient G_4 is applied further to eliminate unwanted

signals. To improve the suppression of the water signal, a pair of CHESS pulses can be applied at the beginning of the sequence. As described previously, the water resonance can be partially inverted allowing for recovery of desired signal at the water chemical shift. In the implementation shown here, spoiler gradients, G_1 and G_2 , are applied along the x and y axes, respectively, while the G_3 and G_4 gradients are applied along the x , y , and z axes simultaneously to minimize any residual water signal that may arise from accidental gradient rephasing.

This approach provides an optimum S/N and peak shapes but is inferior in performance to gradient coherence selection techniques for water elimination.

9.4 Gradient-Enhanced z Filter

To improve on the HSQC with zz filters, a gradient form of the z filter was developed and added to the sequence as shown in Figure 13.⁴⁰ This filter consists of two $90^\circ(^1\text{H})$ pulses with a gradient in between. The first pulse of the filter, $90^\circ_y(^1\text{H})$, rotates the in-phase magnetization (i.e. protons coupled to X) to the z axis. The unwanted magnetization is left in the transverse plane, which is then dephased by the spoiler gradient G_5 . The desirable component of the magnetization, which is aligned along the z axes is then read by the final $90^\circ(^1\text{H})$ pulse. This filter resembles a conventional z filter,⁴⁵ but has the advantage of full sensitivity, since the desired magnetization that enters the filter is completely aligned along a single axis. Unlike conventional z filters which use multiple delays and hence require multiple acquisitions, the gradient z filter accomplishes the filtering in a single acquisition. As illustrated in Figure 14, this method yields full sensitivity, pure absorption peak shapes, and good elimination of water. Furthermore, loss of signal associated with conventional water suppression and the requirement for additional phase cycling to improve suppression is avoided. This method, applied without the CHESS pulse and with z axis only gradients, was found to outperform nongradient methods in terms of solvent and artifact suppression, based on a comparable recording time.⁴²

Figure 13 Pulse sequence for gradient-enhanced z -filtered (GEZ) HSQC. This sequence contains two gradient zz filters G_3 and G_4 and one gradient-enhanced z filter G_5 . Additional water elimination can be achieved via the two CHESS pulses (G_1 and G_2) which precede the sequence. (Reproduced by permission of Academic Press from John et al.⁴⁰)

Gradient z and zz units have also been used to improve ^{13}C resolution in an HSQC–NOESY experiment.⁴⁴

9.5 SWAT Gradients

In the *switched acquisition time* (SWAT) gradient method,⁴⁵ the N type (0, +1, ..., −1) and P type (0, −1, ..., +1) coherence pathway signals are alternately and individually acquired on alternate sampling points of the digitizer. Since the signals from the N type and P type pathways are in an easily separable format, pure phase 2D spectra with quadrature detection in both dimensions can be reconstructed from a single acquisition. The basic idea of the SWAT gradient method is to sample at twice the Nyquist frequency, inserting appropriate gradient pulses between digitizer sampling points, to rephase alternatively the desired coherence. Ordinarily, in a gradient COSY spectrum, either the N type or the P type coherence pathway would remain dephased and unobserved during the acquisition period. The data can be processed to yield pure absorption lineshapes in a number of ways. Although, the SWAT method is quite demanding on gradient switching time, it is the only method which achieves pure phase fully quadrature multidimensional data in a single acquisition per t_1 frame.

10 SPATIAL TOOLS

The rf coils used in high resolution NMR are designed to produce a homogeneous B_1 magnetic field. In practice, homogeneous B_1 fields are achievable in the transverse plane of sample volume and over most the detectable volume along

the z axis. Normally, the transition band, the region of sample volume in which the B_1 field strength goes from its maximum value to zero, is responsible for the B_1 inhomogeneity that can lead to artifacts in multiple pulse NMR experiments. A separate problem that can occur at the coil extremes is that the lineshape of the NMR signal can be distorted by bulk magnetic susceptibility effects from the ends of the sample volume and the end of the NMR sample tube. Like B_1 inhomogeneity, this lineshape distortion can be a problem, especially for observation of protons in aqueous solutions where the water signal must be eliminated or reduced. The principle of slice selection can be applied to eliminate this B_1 inhomogeneous signal in high-resolution NMR.

10.1 B_1 Inhomogeneity and Transition Band Suppression

Gross rf coil inhomogeneity can be visualized via spatial projections along the z axis (so-called z profiles). A z profile of a 180° pulse generated by a typical rf coil is shown in Figure 15(a). Comparison with the 90° pulse z profile from the same coil [Figure 15(b)] illustrates the gradient of B_1 field (transition bands) that occurs at the top and bottom of the coil. In the 180° pulse profile, signal is not detected where a 180° rotation of

Figure 15 z profiles of an (a) 180° rf pulse, (b) 90° rf pulse, (c) composite 90° rf pulse, (d) 90° rf pulse following transition band suppression (TBS), and (e) composite 90° rf pulse following TBS

spins has occurred, but is detected in the sample volume which does not experience a 180° flip. These transition band regions can be reduced slightly by employing a composite 90° pulse as illustrated by the z profile in Figure 15(c). In the transition band suppression (TBS) method,⁴⁶ signals from these regions of coil volume are selectively excited and then eliminated by gradient dephasing. Slice selection is achieved by application of one or more frequency selective pulses during a constant z gradient. In practice, multiple pulses work better because of the differences in B_1 of the region to be suppressed. While this effectively eliminates signal from these unwanted regions of the coil volume, care must be exercised in choice of pulse design to avoid excitation of the spins within the region of homogeneous B_1 . Figure 15(d) shows a 90° pulse profile of the sample following application of TBS, and Figure 15(e) shows the combined effect of TBS and a composite 90° pulse.

10.2 Improvements in WEFT and Reduction of Susceptibility Artifacts

One application of TBS is the reduction in the susceptibility water hump which is often observed in a very short samples. In essence, this is the slice selective version of a matched susceptibility plug.

Spatial differences in both B_0 and B_1 homogeneity also limit the effectiveness of water suppression by T_1 inversion recovery methods such as WEFT. A water elimination technique was described earlier using gradient dephasing in which the duration of the relaxation delay is used to recover the biopolymer spins at the water chemical shift. The TBS approach can be used to limit the effects of B_1 inhomogeneity and significantly reduce the amount of signal left at the water 'null'.

The first practical test of TBS was its incorporation into the phase sensitive version of gradient enhanced DQF COSY. The pulse sequence is shown in Figure 16. Water is first selectively excited using a crafted rf pulse and dephased by application of an x gradient. The residual water spins are then partially inverted and transverse magnetization dephased by application of a y gradient pulse. This is followed by a recovery period

during which the inverted water spins relax to a 'null'. During this recovery period, typically 200 ms, the transition band slices are excited and dephased using a z slice gradient. The water elimination is followed by a phase sensitive gradient enhanced DQF COSY sequence. Coherence is selected using a 1:–2 ratio of gradients applied simultaneously along the x , y , and z axes. The careful choice of gradient axes during the water elimination period and for coherence selection is important to avoid unwanted rephasing of water signal. This approach was tested on a 1 mM sample of ubiquitin in 90% H_2O . As demonstrated by the contour plots of these data shown in Figure 17, water is nearly eliminated and correlations are observed unperturbed, even at or near the water chemical shift.

10.3 Field Maps and Shimming

One advantage of gradients is that you can make images with them. 3D phase or frequency maps are in effect images of the inhomogeneity experienced by the sample. Shim coil fields can also be directly characterized by measurement of a set of field maps with known shim current offsets. The foregoing information should be sufficient to determine in a noniterative way, the optimum corrected field. This approach to shimming, common to in vivo NMR, may become a significant advantage for three-axis gradient systems in high resolution NMR (*Shimming of Superconducting Magnets*).

11 SUMMARY

By effectively replacing the functions of phase cycling with a single-step, pulse field gradients are used to suppress artifacts, extend resolution in the evolution domains of multidimensional NMR and, where S/N allows, reduce total data collection time. Further, B_0 field gradients provide unmatched levels of water elimination, with reduced dependence on the effects of lineshape, magnetization transfer, and dynamic range. With continued improvements in performance and availability, gradients are likely to become a routine part of high-resolution NMR.

1 INTRODUCTION

1.1 Historical Aspects

NMR of flowing systems has been of interest since the early 1950s. For example, Suryan's study¹ in 1951 demonstrated a fivefold increase in the intensity of flowing water in comparison with a static water sample. This increase in signal strength is observed only when there is sufficient time for equilibration of the magnetization in the magnetic field before the signal is monitored (vide infra). An early general review of the subject of flow NMR is contained in a book by Zhernovoi and Latyshev² as well as a later review by Jones and Child.³ During the 1950–1970s, pulsed NMR techniques were developed to measure flow rates, study dynamic flow patterns (laminar, plug, etc.), and measure (or alter) nuclear spin–lattice relaxation rates in flowing fluids. For example, the Carr–Purcell pulse sequence ($90^\circ_x, \tau, 180^\circ_x, 2\tau, 180^\circ_x, 2\tau, \dots$), and related spin echo sequences in the presence of PFGs, evolved as common tools to study both flow and self-diffusion. The amplitude and phase of the echo after the 180° pulse are dependent on the dynamic process involved. A well known distinction between the spin echo generated by flow (coherent) and self-diffusion (dissipative) is the attenuation of the spin echo and phase shift, respectively, for these two dynamic processes. Seminal studies by Singer,⁴ Packer,⁵ Stejskal,⁶ Garroway,⁷ and Hemminga and deJager⁸ led to the development of techniques for measuring self-diffusion, flow rates, and flow patterns (e.g. plug versus laminar flow) during the 1960s and 1970s for both static and flowing samples. For more depth on these topics, the reader should consult *Diffusion and Flow in Fluids*; *Diffusion Measurements by Magnetic Field Gradient Methods*; *Diffusion in Porous Media*, and *Diffusion in Rare Gas Solids* (as well as recent reviews by Stepišnik,⁹ Caprihan,¹⁰ Chingas,¹¹ and Altobelli.¹²

During the 1970s, Sykes¹³ and Fyfe¹⁴ pioneered the development of flow NMR approaches to follow the intermediates in chemical reactions. One of the most significant developments during this time period was the advent of the pulsed FT technique by Ernst and Anderson.¹⁵ The FT NMR technique helped facilitate flow chemical reaction monitoring and

on-line NMR detection of liquid chromatography (LC–NMR) fractions. This major development coupled with the advent of mass data storage devices accelerated the implementation of these flow NMR techniques. During the next two decades, flow NMR instruments and probes were developed for a wide range of experimental conditions, including: (1) NMR measurements at high pressure and temperatures, (2) surface coils for in situ flow monitoring, and (3) homogeneous higher field superconducting magnets with large volumes.

During the 1980–1990s, MRI techniques were reported for the measurement of blood flow profiles in animal and human subjects. A number of methods for magnetic and chemical 'tagging' of a flowing bolus have been introduced. For biological flow studies, infusion of water (^2H , ^{17}O labeled), trifluoromethane (^{19}F), sodium (^{23}Na), and phosphorus (^{31}P) compounds have been reviewed by Neil.¹⁶ The use of MRI and improved PFG techniques have further extended the types of flow velocity patterns (turbulent flow, granular flow, etc.) that can be studied. These latter topics are discussed in detail elsewhere in the Encyclopedia (see *Diffusion: Clinical Utility of MRI Studies*; *Diffusion and Perfusion in MRI* and *Whole Body Magnetic Resonance Angiography*).

1.2 Basic Concepts of Flow NMR

In order to appreciate some of the basic differences between static and flow NMR experiments, consider a flowing bolus (rounded mass) in the detector region (Figure 1). If we define a simple plug flow pattern ($F = V/t$), a given bolus has residence times t_a , t_b , and t_c in regions A, B, and C, respectively. If a given bolus resides for a relatively short time, $t_a \ll T_{1a}^x$ in region A, and the low magnetic field B_0^L is small ($B_0^L \sim \text{Earth's magnetic field}$), the magnetization monitored will be determined by the high magnetic field magnetization.

Figure 1 A flowing bolus in the detector region of an NMR instrument

In order to achieve a monitored signal that approaches the full equilibrium Boltzmann magnetization (M_0^H), it is clearly necessary to have a long residence time in the high magnetic field relative to the high field spin–lattice relaxation time, $t_t \gg T_{1bc}^x$. This is also sometimes expressed by treating flow as a relaxation process.^{2,3} For example, the observed flow spin–lattice relaxation rate ($1/T_1$) flow in the presence of flow can be defined as

$$\left(\frac{1}{T_1^x}\right)_{\text{obsd}} = \left(\frac{1}{T_1^x}\right)_{\text{static}} + \frac{1}{t_t} \quad (1)$$

For nuclei with long spin–lattice relaxation times (e.g. ^{13}C , $T_1^x = 10\text{--}100\text{ s}$), the observed relaxation rate is dictated by the total residence time in the high magnetic field, before detection ($t_t = t_b + t_c$). Thus, measuring the monitored magnetization as a function of flow rate is one method of measuring spin–lattice relaxation times [equation (1)]. On the other hand, it is sometimes desirable to circumvent this T_1 ‘bottleneck’ by installing a large equilibration volume before the detector cell (region B). A second approach is to have the bolus flow over a stable free radical system (e.g. a silica immobilized nitroxide) in region B. In this manner, it is possible to enhance significantly the spin–lattice relaxation rate by strong nuclear–electron interactions. In either of these approaches, the intent is to recover the full equilibrium Boltzmann magnetization independent of the flow rate.

It is also useful to consider a second experiment when B_0^L is not zero. In this case, it is assumed that the sample has equilibrated in the lower magnetic field for a time that is long relative to the low magnetic field spin–lattice relaxation time, $t_a \gg T_{1a}^x$. The monitored magnetization in the high magnetic field (B_0^H) will now consist of low and high magnetic field magnetization components (M_{xy}^L and M_{xy}^H). In fact, the monitored magnetization (region C) can be dominated by the low magnetic field magnetization M_{xy}^L , if the volumes in regions B and C are small and flow transfer is rapid, $t_t \ll T_{1bc}^x$ (see Section 4.2). Under these conditions, the monitored magnetization is linearly dependent on B_0^L . This suggests one of the simplest methods for ‘magnetic tagging’ and provides a convenient method of monitoring the low field magnetization, but with high magnetic field spectral resolution. An alternative experiment can also be employed in which the flow is reversed and the flowing bolus is allowed to develop the high magnetic field magnetization (M_0^H), but is monitored in a low magnetic field (e.g. the Earth’s magnetic field).

One can also envision several other possible methods for flow rate measurements by magnetic tagging of a given bolus (Figure 2). In one simple experiment, a uniformly homogeneous magnetic field (B_0) for both the upstream and downstream coils is employed in a two-coil system. In this approach, the upstream coil (region A) tags a flow segment by inverting the magnetization. If significant spin–lattice relaxation does not occur before the flow segment reaches the monitoring detector (region B), the inverted segment can be detected and the flow rate determined. There are many variations on this basic approach which have been reported for ‘tagging’ a flowing bolus.

A second consequence of flow is the effective residence time of the bolus in the detector cell, t_c . The average residence time

Figure 2 Flow rate measurement by magnetic tagging of a bolus using a two-coil system

of the bolus in the detector cell, V_{cell} , can be expressed as

$$t_c = \frac{V_{\text{cell}}}{\bar{v}} \quad (2)$$

where the mean velocity ($\bar{v}$) must be used. The mean velocity is defined because for other flow patterns (e.g. laminar) the velocity is a function of the distance from the detector cell walls. Once again, treating flow as a relaxation process, the ‘lifetime broadening’ can be expressed as

$$\left(\frac{1}{T_2^x}\right)_{\text{obs}} = \left(\frac{1}{T_2^x} + \frac{1}{T_2'}\right)_{\text{static}} + \frac{1}{t_c} \quad (3)$$

It is apparent from equation (3) that the observed NMR linewidth ($\Delta\nu_{\frac{1}{2}}$) can be significantly broadened at high flow rates since the static component contains contributions from the spin–spin relaxation rate and the magnetic field inhomogeneity. For example, Fyfe¹⁷ has reported ^1H NMR linewidth data for flowing ethylbenzene using a 5 mm o.d. flow tube. A linear plot [equation (3)] was obtained as a function of flow rate with linewidths ranging from 2.2 Hz (static) to 8 Hz (flow, 120 mL min^{-1}).

The simple models illustrated (Figures 1 and 2) provide only a cursory understanding of some of the basic concepts in the flow NMR experiment, and are rarely an adequate description of flow NMR under most experimental conditions. The experimental picture is generally more complicated because of the presence of laminar, turbulent, or other more complex flow patterns. In addition, self-diffusion effects of the flowing bolus cannot be ignored. The reader should consult other articles in the Encyclopedia for other treatments of this subject (see *Diffusion and Flow in Fluids*).

2 MONITORING CHEMICAL REACTIONS AND INTERMEDIATES IN FLOWING LIQUIDS

2.1 Chemical Reaction Kinetics and Labile Intermediates

The spectroscopic investigation of chemical reaction intermediates has provided a wealth of information regarding the kinetics and mechanisms of chemical reactions. In situ spectroscopic approaches have the advantage of monitoring labile intermediates without the necessity of direct isolation from reaction mixtures. Although many spectroscopic approaches have better sensitivity than NMR, the diagnostic character of NMR provides unique spectroscopic characterization of intermediates in organic, inorganic, and biological systems. The flow and stopped flow NMR experiments enable chemical reaction intermediates to be monitored and kinetic measurements performed for reaction times down to the millisecond timescale. In 1972, an apparatus for flow NMR studies of reaction intermediates was described by Bargon.¹⁸ In the same year, Asahi and Mizuta¹⁹ reported flow ^1H NMR results for the reaction of thiamine with the hydroxide ion.

Although the advent of FT NMR instrumentation has enabled fast acquisition of rate data, nuclei with long relaxation times still require equilibration in the magnetic field for long periods of time relative to the spin–lattice relaxation time (see Section 1.2). Kühne et al.²⁰ have presented a theoretical formalism for the lineshape analysis of transient intermediates in nonequilibrium chemical reactions ($A \rightarrow B$) and reported a stopped flow ^1H NMR study demonstrating this approach. It is noteworthy that their treatment not only includes lineshape changes due to the finite lifetime of the molecule, but also the phase and dispersive lineshape changes for the corresponding product molecule. The basic hydrolysis (NaOH) reaction of methyl formate in D_2O was used as an experimental test of their approach (Scheme 1).

Excellent agreement was observed between the experimental and theoretical lineshapes for the methyl hydrogen resonance [Figures 3(a) and (b)] and the formate hydrogen resonance [Figures 3(c) and (d)]. From their data, a second order rate constant of $k_{\text{av}}^{(2)} = 80 \pm 10 \text{ L mol}^{-1} \text{ s}^{-1}$ (D_2O , 28.8°C) was obtained. A minimum dead time for their apparatus was $\sim 2 \text{ ms}$.

In 1978, Fyfe et al. reviewed flow and stopped flow NMR studies of reaction intermediates in chemical reactions.¹⁴ In one of their studies, they examined the reaction of 3,5-dinitrocyanobenzene (**1**) with one equivalent of solution methoxide.²¹ As illustrated in Figure 4, the static spectrum [compound (**1**)] exhibits two resolved ^1H NMR signals, whereas, at a flow rate of 30 mL min^{-1} five ^1H NMR signals were observed. The three signals of nearly equal intensity in this spectrum were assigned to the aromatic hydrogen in complex (**2**). The other two aromatic signals (2:1 ratio) were assigned to the thermodynamically less stable isomer (**3**). At higher flow rates (50 mL min^{-1}) the relative intensities of the isomer (**3**) increase; however, when the flow was stopped

Figure 3 Experimental and fitted theoretical lineshapes for the hydrolysis of 0.15 M methyl formate with 0.63 M deuterated sodium hydroxide in D_2O . The fitted parameters were $k_1 = 45 \text{ s}^{-1}$ and $t_d = 3 \text{ ms}$. (a) Experimental and (b) theoretical methyl hydrogen resonance, and (c) experimental and (d) theoretical formate proton resonance lineshapes. (Reprinted by permission from Kühne et al.²⁰)

(Figure 4, bottom spectrum), only the signals due to the more stable complex (**2**) were observed. By varying the flow rate, and monitoring signal intensities a description of the kinetics of the system was obtained. In this manner, the half-life for the complex (**3**) was found to be 0.94 s at 30°C . A minimum mixing time of $\sim 20 \text{ ms}$ was estimated for their apparatus (Scheme 2).

In a more recent study by Trahanovsky and Fischer,²² the unstable molecule benzocyclobutadiene (**5**) was monitored for the first time by flow ^1H NMR (Figure 5). At high flow rates (45 mL min^{-1}) only (**5**) is observed; however, at low flow rates (**5**) has been shown to dimerize to (**6**) (Scheme 3).

Although (**5**) has been isolated in an argon matrix at 20 K , the high reactivity of this labile molecule has made it difficult to study at ambient temperatures. Several other intermediates in organic and inorganic reactions have been monitored by the flow and stopped flow NMR technique. For example, Trahanovsky and co-workers²³ have also utilized flow ^1H NMR to observe the labile molecule *o*-xylylene generated from *o*-quinodimethane. Tan and Cocivera^{24,25} have studied the reaction of 4-formylpyridine with amino acids, imidazole, and

Scheme 1

Figure 4 Representative ^1H NMR spectra recorded at 100 MHz, 0.5 M in DMSO, showing the ring proton absorptions of 3,5-dinitrocyanobenzene alone (top spectrum) and during its reaction with one equivalent of the methoxide ion (in 87.5% DMSO/12.5% MeOH) under the conditions of flow rate indicated. (Reprinted by permission from Fyfe et al.¹⁴)

Scheme 2

DL-alanylglycine using the stopped flow ^1H NMR approach. In another study, Cocivera examined the dehydrohalogenation reaction of 2-chloropropanoyl chloride.²⁶

Recently, Funahashi and co-workers²⁷ have designed a high-pressure ^1H NMR probe for stopped flow measurements at pressures <200 MPa. In this study, the substitution reactions of $(\text{CH}_3)_4\text{Sn}$ with I_2 in HCCl_3 and the solvent exchange reaction of the Al^{3+} ion with dimethylformide were examined. The volumes of activation measured by this approach were -2.2 ± 0.8 and $-24.9 \pm 3.8 \text{ cm}^3 \text{ mol}^{-1}$, respectively. Albert²⁸

has reported monitoring the electrochemical reaction of 2,4,6-tri-*t*-butylphenol by continuous flow ^{13}C NMR. Davis and co-workers²⁹ have reported in situ continuous monitoring of the vapor phase reaction of ^{13}C labeled 2-propanol vapor on a zeolite HZSM-5 catalyst at $100\text{--}180^\circ\text{C}$. In 1986, flow and stopped flow NMR studies were reviewed by Selivanov and Ershov.³⁰

2.2 Biochemical Reaction Monitoring

Although NMR is an excellent tool for monitoring chemical reactions, the technique is usually limited to nuclei with high sensitivity (e.g. ^1H , ^{31}P) or samples which can be isotopically enriched (e.g. ^{13}C). The noninvasive nature of the NMR approach is an attractive feature of this approach and is especially applicable to monitoring biological reactions. In addition, the NMR experiment can provide unique information regarding conformational changes, ligand binding, and exchange rates, as well as monitoring complex reactions.

In this area, Grimaldi and Sykes¹³ reported a pioneering study of conformational changes of concanavalin A in the presence of Mn^{2+} , Ca^{2+} , and α -methyl-D-mannoside using stopped flow NMR.

Biochemical processes have been extensively monitored utilizing stopped flow and flow ^{31}P NMR. The high NMR sensitivity and large chemical shift range are inherent advantages of the ^{31}P nuclide. Jardetzky and co-workers³¹ have reported continuous flow ^{31}P NMR experiments designed to monitor changes in mammalian cells (Chinese hamster ovary cells) in response to stresses, such as starvation, low temperature, and pH. In another study, extracorporeal observation of blood flow under in vivo conditions was described using a bypass from the animal (e.g. a dog). In this manner, phosphorus metabolites [e.g. adenosine triphosphate (ATP)] were continuously monitored.³² More recently, Graaf et al.³³ have described a continuous flow NMR bioreactor for in vivo studies of microbial cell suspensions. Chen and Bailey³⁴ have reported a similar on-line NMR system for monitoring bacterial suspensions under aerobic and anaerobic conditions. To illustrate this approach, the ^{31}P NMR spectra obtained for an *Escherichia coli* culture (MG1655) at cell densities of 45 g dry weight L^{-1} under aerobic and anaerobic conditions are provided (Figure 6). Significant changes in these ^{31}P spectra are evident following the switch from aerobic to anaerobic conditions. For

example, the intracellular NTP levels decrease in the shift from aerobic to anaerobic conditions. It was concluded that anaerobic glycolyzing cells contained a much smaller amount of NTP (20–50% lower) than cells in aerobic conditions. An in vivo flow ^{31}P NMR study of a functional phosphagen in the metabolism of a microscopic nematode, *Steinernema carpocapsae*, has also been reported.³⁵

The development of surface coils in the early 1980s by Ackerman et al.³⁶ provided new technology for in situ measurements of blood flow, oxygen uptake, and phosphorus metabolism in small animals.^{36–38} For example, Eleff et al.³⁷ employed surface coils to measure in situ cerebral blood flow in cat brains. The high energy phosphate metabolites, phosphocreatine, inorganic phosphate, and ATP, were monitored by ^{31}P NMR. In addition, ^{19}F (blood flow via HCF_3), ^{23}Na , and 1H (lactate) NMR techniques were employed in this multinuclear flow magnetic resonance study. In another study by Ackerman et al.,³⁸ 2H NMR and ^{31}P NMR were used to investigate blood flow and metabolism of rat hind limb muscle during sepsis.

Although limited by sensitivity, studies of biological monitoring with less sensitive NMR nuclides (^{13}C) have been reported.^{39–41} Albert and Bayer³⁹ have reported in vivo metabolism studies of ^{13}C -labeled phenacetin in an isolated perfused rat liver by continuous flow ^{13}C NMR. Also, a study of Ca^{2+} ion binding to β -trypsin and α -chymotrypsin using ^{43}Ca and ^{113}Cd flow NMR was reported.⁴¹ Other examples of monitoring biological processes under flow (and nonflow) conditions are discussed in MRI articles of the Encyclopedia.

3 DIRECT COUPLING OF LIQUID CHROMATOGRAPHY AND NMR (LC-NMR)

In 1978, Watanabe and Niki⁴² reported the results for direct coupling of high-performance liquid chromatography (HPLC) to 1H NMR with stopped flow detection. During the next 2 years, Bayer et al.,⁴³ Buddrus and Herzog,⁴⁴ and Haw and Dorn⁴⁵ extended the approach, but with continuous flow 1H NMR detection (LC- 1H NMR). During the last 15 years, numerous LC-NMR studies have been reported, with reviews written in 1984, 1986, and 1988.^{46–48} One of the major advantages of NMR in comparison with other commonly employed chromatographic detectors is the high information content present in the NMR chemical shift dimension. The inherent advantage of monitoring the local electronic environment at each nonequivalent nuclear site in a molecule has distinct advantages in comparison with other chromatographic detectors (ultraviolet, refractive index etc.). This is a particularly relevant point for those applications involving isomer identification and/or analysis of complex nonvolatile mixtures. The noninvasive nature of the NMR detector also has distinct advantages for characterization of air sensitive and/or light sensitive labile compounds.

The major limitation of NMR as a chromatographic detector is the detection limits (Table 1). Even with the advent of higher magnetic field NMR spectrometers (500–600 MHz, 11.8–14.1 T), typical detection limits for continuous flow 1H NMR are in the 10^{-5} – 10^{-6} g range for chromatographic time windows of 15–30 s. As noted in Table 1, fluorescence and mass spectrometry detectors have a significant sensitivity advantage, but the structural information available from

Figure 6 Phosphorus-31 spectra during aerobic and anaerobic glucose glycolysis of *E. coli* in early stationary phase: (a) aerobic spectrum and (b) anaerobic spectrum, both acquired at a cell density of about 45 g dry weight L^{-1} SP, sugar phosphate; Pi^{in} , intracellular inorganic phosphate; Pi^{ex} , extracellular inorganic phosphate; NTP, nucleoside triphosphate; NDP, nucleoside diphosphate; NAD(H), nicotinamide adenine dinucleotide; UDPG, uridine diphosphoglucose. (Reprinted by permission from Chen and Bailey³⁴)

Table 1 Approximate Detection Limits for Various Spectroscopic Approaches

Technique	Detection Limit (g)
Mass spectrometry	10^{-10} – 10^{-12}
Fluorescence spectrometry	$\sim 10^{-12}$
Infrared spectrometry	10^{-6} – 10^{-9}
Inductively coupled plasma–atomic emission spectrometry	10^{-6} – 10^{-9}
Refractive index	$\sim 10^{-6}$
NMR	10^{-4} – 10^{-6}

these detectors is limited. In fact, most of these common spectroscopic detectors have a 10^2 – 10^6 advantage in comparison with even the favorable ^1H nuclide. Because of this sensitivity limitation, the coupling of liquid chromatography and NMR spectroscopy usually requires larger sample injection volumes (100–500 μL) in comparison with most HPLC experiments. These higher injection volumes can also lead to degradation of resolution in the chromatographic dimension and corresponding peak band broadening. For flow cell volumes of 20–200 μL , typical flow rates of 1–4 mL min^{-1} generally do not cause significant lifetime line broadening in the ^1H NMR chemical shift dimension.^{46–48} As previously discussed, an important requirement is equilibration of the flowing bolus in the magnetic field before NMR detection. These and other conditions necessary for quantitative flow LC–NMR measurements have been reported.⁴⁹

A second problem originally anticipated for the LC– ^1H NMR technique was the limited choice of solvents compatible for chromatography analysis. Specifically, chromatographic solvents which do not contain extensive ^1H NMR background signals are certainly more desirable. This problem has been largely alleviated by the use of deuterated, chlorinated, and/or fluorinated solvents. In another approach supercritical fluid chromatography (SFC) coupled with ^1H NMR has the advantage that certain common supercritical solvents (e.g. CO_2) do not contain hydrogen.⁵⁰ However, for certain chromatographic separations (e.g. reversed phase), large residual ^1H NMR background signals are usually present in solvents, such as (D_2O , H_2O) or (CD_3OD , CD_3OH). In these cases, solvent suppression sequences have been successfully employed to eliminate one or more remaining spectral lines. Laude and Wilkins have utilized a 1–1 hard pulse sequence for solvent suppression (97:3, D_2O /acetonitrile) in a reverse phase LC– ^1H NMR separation of the nucleosides uridine, cytidine, and adenosine.^{51,52} More recently, Albert and Bayer have employed a binomial $1\bar{3}3\bar{1}$ sequence for solvent suppression of a 50/50 water/acetonitrile solvent system in a reversed phase separation of several aromatic compounds (70 μg each).⁵³ The LC– ^1H NMR (500 MHz) contour plot for this separation is illustrated in Figure 7. In other work by this group, LC– ^1H NMR stopped flow 2D COSY data were obtained for a metabolite of 2-[(dicyclopropylmethyl)amino]- Δ^2 -oxazoline dihydrogenophosphate.⁵⁴ Also, a French group⁵⁵ has reported an LC– ^1H NMR study of an epoxy–amine system.

One of the more exciting recent developments in the area of LC–NMR is the work reported by Hatada and co-workers. In several studies, this group utilized gel permeation chromatography directly coupled to ^1H NMR (GPC– ^1H NMR) to analyze several different soluble homopolymers, copolymers, and oligomers.^{56–59} In one study, chloral oligomers

Figure 7 Proton NMR chromatogram (contour plot, 500 MHz) of a separation of phenol ($t_R = 6$ min), benzaldehyde ($t_R = 12$ min), acetophenone ($t_R = 13$ min), nitrobenzene ($t_R = 23$ min), methyl benzoate ($t_R = 25$ min), anisole ($t_R = 30$ min), and benzene ($t_R = 34$ min) (70 μg each; column, 250 $\times$ 4.0 mm; flow-rate 1 mL min^{-1}). (Reprinted by permission from Albert and Bayer⁴⁸)

were separated in both the chromatographic and ^1H chemical shift domains into dimer, trimer, tetramer, pentamer, hexamer, and heptamer fractions in the GPC– ^1H NMR profile.⁵⁶ In a GPC– ^1H NMR study of isotactic PMMAs containing a single *t*-butyl end group, the molecular weights were directly determined from integration of the *t*-butyl and methoxy ^1H NMR signals.⁵⁹ The on-line GPC– ^1H NMR profile for isotactic PMMA is shown in Figure 8, and the corresponding ^1H NMR detected GPC curves are shown in Figure 9. In the latter figure, the refractive index curves are similar to the NMR data, but displaced in time because of differences in the void volumes of the two detectors. A linear plot of $\log(\bar{M}_n)$ versus elution time was obtained from the ^1H NMR data profile.

To date, the LC–NMR technique has been employed for all common liquid chromatographic modes, including normal phase, gel permeation, reversed phase, and supercritical fluid chromatography. The technique has also been extended to other nuclei with good sensitivity (LC– ^{19}F NMR).⁶⁰ Sensitivity constraints will undoubtedly continue to limit extension of the LC–NMR technique to other nuclei with lower sensitivity (e.g. ^{13}C). Nevertheless, anticipated further instrumentation advancements could help alleviate this situation (vide infra).

Figure 8 On-line GPC–NMR data of isotactic PMMA ($\bar{M}_n = 12\ 600$). Cross section at 3.60 ppm (*) where the methoxy proton resonates give the ^1H NMR detected GPC curve (see Figure 9). (Reprinted by permission from Hatada et al.⁵⁹)

Figure 9 The ^1H NMR detected GPC curves of the isotactic PMMAs with $\bar{M}_n$ values of 12 600, 5260, and 3160. These curves were obtained by plotting the intensity of the methoxy proton signal (3.60 ppm) against elution time. The refractive index (RI) detected GPC curves are also shown. (Reprinted by permission from Hatada et al.⁵⁹)

4 SIGNAL ENHANCEMENT

4.1 Recycled Flow

As previously indicated, Suryan's observation of a fivefold increase in the intensity of a flowing water sample represents one of the first applications of flow NMR.¹ A similar enhancement (threefold) for a flow ^{13}C NMR study of benzene was observed by Forsén and Rupprecht.⁶¹ Mitchell and Phillips⁶² also utilized a flow system to detect low levels of H_2O (in D_2O) with higher rf power levels. In another early flow ^1H and ^{19}F NMR study by McIvor, signal enhancements for fluorinated hydrocarbons were reported.⁶³ It is noteworthy that these increases in the signal-to-noise ratio are per unit time and are only possible when there is sufficient sample quantity for magnetic field equilibration prior to monitoring in the active region (see Section 1.2). Thus, this flow method of enhancement is only possible by the continual influx of 'freshly equilibrated' spins. More recently, the same experiment has been described in terms of a recycled flow NMR experiment. Wilkins and Laude have reported reduced measurement times for long-relaxing nuclei, such as, carbonyl and quaternary carbon atoms in recycled flow ^{13}C NMR.^{64–67} Laude and Wilkins have also utilized a recycled flow ^{29}Si NMR experiment for end-group analysis of siloxane polymers ($\bar{M}_n$ values, 495–3773).⁶⁷ The flow NMR method was found to be more effective than using paramagnetic relaxation reagents for leveling spin–lattice relaxation times and minimizing nuclear Overhauser effects. A factor of 3–5 improvement in analysis time was reported by this group in comparison with static NMR measurements.

Fyfe and co-workers⁶⁸ introduced a different method of leveling spin–lattice relaxation times in flowing NMR studies which avoids the use of large equilibration volumes in the magnetic field. Specifically, their approach employed the use of stable free radicals (nitroxides) immobilized on a substrate (silica) placed in the flowing stream before detection. The flowing liquid exhibited significant increases in the effective nuclear relaxation rates because of efficient electron–nuclear relaxation processes at the liquid–substrate interface. The approach was not only important for decreasing spin–lattice relaxation times for the flowing fluid, but quantitative peak intensities were also obtained.

4.2 Flow DNP

Dorn and co-workers have reported^{69–73} a transfer DNP experiment for signal enhancement which was originally suggested by Motchane⁷⁴ and later by Richards.⁷⁵ The experiment involves polarizing a flowing bolus in a low magnetic field, but monitored in a high magnetic field. (In some respects this experiment is similar to field cycling experiments—see *Field Cycling Experiments*.) Sagdeev and co-workers have also reported a similar low to high magnetic field flow transfer apparatus for CIDNP and DNP experiments.⁷⁶ This approach provides dramatic improvements in signal enhancement when compared with the classic static DNP experiment.

As background to this approach, numerous static DNP studies have been reported and reviews written for both liquid^{75–79} and solid⁸⁰ samples. Although the DNP technique holds great promise as a means of enhancing the signal for many NMR nuclides (e.g. ^{13}C , ^{31}P , ^{15}N , etc.), a number of difficulties have hampered the widespread use of the DNP technique. The DNP polarization A can be expressed in the following simplified form^{75,77–79} for the time dependent Overhauser effect:

$$A = \left[\frac{\bar{M}_z - M_0}{M_0} \right] = \rho f s \left(\frac{\gamma_e}{\gamma_I} \right) \quad (4)$$

where γ_I and γ_e are the magnetogyric ratios for the nuclear and electron spins, respectively, and the coupling (ρ) and leakage (f) factors are defined in terms of the appropriate transition probabilities W_2^D , W_0^D , W_1^D , etc., for the nuclear–electron interaction,

$$\rho = \frac{(W_2^D - W_0^D - W_0^{\text{Sc}})}{(W_2^D + W_0^D + W_0^{\text{Sc}} + 2W_1^D)} \quad (5)$$

The coupling factor for the Overhauser effect can have any value between -1.0 for a purely scalar interaction, to a dominant dipolar interaction $W_0^{\text{Sc}} \simeq 0$, which has a limiting value of $+0.5$ in the extreme narrowing limit, $\omega_e \tau_c \ll 1$, ($W_0^D : W_1^D : W_2^D = 2 : 3 : 12$). It should be noted that for large macromolecules the extreme narrowing condition will normally not be satisfied. Since the nuclear spin–lattice relaxation rates in the presence and absence of a free radical are given by $(T_1^{xs})^{-1} - (T_1^x)^{-1} = (W_0^D + 2W_1^D + W_2^D + W_0^{\text{Sc}})$ and $(T_1^x)^{-1} = W_1^0$, respectively, the leakage factor can be readily measured (or estimated) from the relationship

$$f = \frac{W_0^D + 2W_1^D + W_2^D + W_0^{\text{Sc}}}{W_0^D + 2W_1^D + W_2^D + W_0^{\text{Sc}} + W_1^0} \quad (6)$$

and

$$f = 1 - \frac{T_1^{xs}}{T_1^x} \quad (7)$$

The electron spin saturation factor (s) is given by

$$s = \frac{S_0 - \bar{S}_z}{S_0} \quad (8)$$

$$\bar{S}_z = \frac{S_0}{1 + \alpha B_{1e}^2 T_1^e T_2^e} \quad (9)$$

where T_1^e and T_2^e are the electron spin–lattice and transverse relaxation times, respectively. Since the microwave power P is proportional to B_{1e}^2 , an inverse plot of enhancement $[A]^{-1}$ versus P^{-1} is normally employed experimentally to obtain A_∞ , the value of the enhancement for complete saturation, $s = 1$. In addition to the Overhauser effect, time independent interactions are important in studies of solid samples.⁸⁰ A solid state effect is an important mechanism in ‘rigid’ samples containing fixed free radical centers and achieves a maximum for $\omega = \omega_e \pm \omega_n$. This is in contrast to the Overhauser effect where the maximum occurs at $\omega = \omega_e$. Also, a direct and indirect thermal mixing effect can occur when there is a large number of fixed free radical centers such that the ESR line is homogeneously broadened. In the direct thermal mixing effect, a maximum enhancement occurs at $\omega = \omega_e \pm \frac{1}{2}\Delta\omega_n$. The case of time independent DNP interactions is treated in more depth in another article (see *Dynamic Nuclear Polarization and High-Resolution NMR of Solids*).

To understand the flow DNP experiment, consider a flowing bolus in the low-to-high magnetic field experiment (Figure 10) without DNP enhancement (no microwave irradiation). A silica phase immobilized nitroxide (SPIN) sample is present in the low magnetic field and is similar to the samples previously described by Fyfe.⁶⁸ It is apparent that the observed magnetization for a flowing bolus (e.g. benzene) at

the high magnetic field detector is dependent on the flow rate. At very low flow rates (or static conditions), the observed NMR signal is dominated by the high magnetic field thermal Boltzmann equilibrated magnetization (M_0^H). However, at sufficiently high flow rates the high magnetic field contribution to the total magnetization decreases dramatically, since the spin–lattice relaxation time (in the absence of the radical) is long relative to the residence time (t_c) in region C. For high flow rates, a significant fraction of the observed signal can result from the low field thermal equilibrated Boltzmann magnetization (M_0^L). That is, the bolus residence time (t_a) in region A is long relative to the significantly shortened spin–lattice relaxation time of the flowing fluid in the presence of the SPIN system. After leaving region A, the bolus is transferred to the high magnetic field detector (region C). For high flow rates, the bolus is transferred via region B in a time that is short relative to the relaxation time in the absence of the radical. Under these conditions, the low field magnetization (M_{xy}^L) will tend to dominate the monitored magnetization at sufficiently high flow rates.⁶⁹

If we now consider the flow DNP experiment, a microwave source ($\omega_e/2\pi = 9.4$ GHz) saturates the electron transition(s) in the low magnetic field B_0^L , and a DNP enhanced flowing bolus is generated. This polarized bolus can then be transferred to the high magnetic field detector. This experiment has the advantage that the polarized bolus is monitored in the high magnetic field in the absence of the radical. Thus, the achievable high field spectral resolution in the chemical shift dimension is only limited by the residual inhomogeneity of the high field magnet and possible flow lifetime broadening. However, even the latter broadening factor can be avoided using a stopped flow transfer DNP experiment.⁷¹

A model has been reported for the flow transfer DNP experiment⁷¹ which assumes plug flow with the bolus having average residence times τ_a , τ_b , and τ_c in regions A, B, and C, respectively. Under the limiting conditions $\tau_a \gg T_{1a}^x$, $\tau_b \ll T_{1b}^x$ and $\tau_c \ll T_{1c}^x$, the model predicts a maximum enhancement in the low-to-high magnetic field transfer experiment of A/K . It should be noted that the maximum observable enhancement monitored at the high magnet field (without relaxation losses) is attenuated by only the ratio K relative to the corresponding high static field DNP experiment (B_0^H). Since typical values of K are of the order of 10^1 – 10^2 , DNP enhancements can easily exceed the thermal Boltzmann magnetization at the monitoring high magnetic field. This is achievable for favorable flow DNP experiments, since the maximum Overhauser enhancement (A) is 10^3 – 10^4 for most nuclides [equation (4)].

To date, enhancements for ^1H , ^{13}C , and ^{29}Si DNP have been reported using the flow transfer DNP approach. Two different stable radical systems have been employed: (1) a solid–liquid intermolecular transfer (SLIT) experiment utilizing SPIN samples^{69,72,73,81,82} or (2) a liquid–liquid intermolecular transfer ($L^2\text{IT}$) experiment in which a stable free radical (e.g. the 2,2,6,6-tetramethyl-1-piperidinyloxy radical, TEMPO) is present in the flowing liquid.^{70,71,73}

The SLIT and $L^2\text{IT}$ transfer ^{13}C DNP experiments have been used to study the collisional dynamics of fullerene- C_{60} dissolved in deuterated benzene (in the presence of TEMPO) as illustrated in Figure 11.⁷² In these experiments the low and high magnetic fields were 0.33 and 14.7 T, respectively ($K = 14.4$). The ^{13}C DNP spectrum exhibits a negative DNP enhancement for fullerene- C_{60} and the solvent C_6D_6 ,

Figure 10 The low magnetic field transfer DNP apparatus. HPLC, high-performance liquid chromatography. (Reprinted by permission from Dorn et al.⁶⁹)

Figure 11 The collisional dynamics of fullerene-C₆₀ dissolved in deuterated benzene (in the presence of the free radical TEMPO), as followed by the SLIT and L²IT transfer ¹³C DNP experiments

indicating that the electron–nuclear interaction with the free radical (TEMPO) is dipolar dominated in both cases. The ultimate DNP enhancements (A_∞) for fullerene-C₆₀ and the solvent (C₆D₆) were -250 ± 20 and -200 ± 20 , respectively. In comparison with deuterated benzene (C₆D₆), a further reduction in the ¹³C DNP enhancement for the larger, more slowly rotating C₆₀ molecule might be anticipated because of a further reduction in the dipolar spectral density and/or the presence of a small scalar contribution.^{77,78} However, the ultimate ¹³C DNP enhancement for fullerene-C₆₀ was remarkably large, $A_\infty = -250 \pm 20$. This observation in conjunction with the absence of even a minor ¹³C NMR scalar contact shift suggests that the nuclear–electron time dependent interaction for fullerene-C₆₀/TEMPO is exclusively dominated by the dipolar mechanism. Assuming that a rotationally modulated mechanism dominates the dipolar interaction, the corresponding rotational correlation time (τ_r) was estimated from the expression for exclusive rotational dipolar diffusion:^{77,78}

$$\rho_D^r = \frac{1}{1.4 + 0.6[J_D^r(\omega_I)/J_D^r(\omega_e)]} \quad (10)$$

$$J_D^r(\omega) = \frac{1}{2\pi b^6} \frac{\tau_r}{1 + \omega^2 \tau_r^2} \quad (11)$$

where b is the nucleus–electron distance in the complex.

An expression similar to equation (10) has been presented for a dominant translational diffusion mechanism, but the spectral density function $J_D^t(\omega)$ has a different frequency dependence.⁸³ Using equations (10) and (11), the experimentally measured value for nuclear–electron coupling ($\rho = 0.095$) leads to the value $\tau_r = 65$ ps for the fullerene-C₆₀/TEMPO complex. The presence of a minor scalar component complicates a similar calculation for the C₆D₆/TEMPO system.

The rotational correlation time can also be estimated from the Stokes–Einstein equation.⁷⁷ Based on the value $\tau_r = 65$ ps, and the viscosity, $\eta \approx 0.65$ cp, a value of $R \approx 0.46$ nm was predicted, which represents the radius of the complex (fullerene-C₆₀/TEMPO). An alternative expression for exclusive translational diffusion leads to a considerably shorter predicted correlation time than the value obtained from the ¹³C DNP measurement. However, a model involving a mixture of rotational and translational diffusion contributions cannot be dismissed.^{77,78} The results of the flow ¹³C DNP study suggest very weak momentary transient bond formation during solution collisions of fullerene-C₆₀ and TEMPO.

In contrast to the case of fullerene-C₆₀ above, selective intermolecular interactions have also been monitored at liquid–liquid and solid–liquid interfaces. To illustrate this point (Figure 12), an L²IT ¹³C DNP study⁷¹ of 1-chlorobutane/TEMPO exhibited a strong scalar enhancement ($A_\infty = +460$) for C-1 (to which the chlorine atom is attached) but dipolar enhancements for carbons C-2 (-200), C-3 (-400), and C-4 (-290). In the corresponding SLIT ¹³C DNP experiment⁷² a strong scalar ¹³C DNP enhancement was also observed at C-1. In contrast, the corresponding ¹H DNP SLIT and L²IT experiments⁷¹ demonstrated only dipolar dominated enhancements for the hydrogens at all four nonequivalent carbons.

Although fullerene-C₆₀ and many hydrocarbons exhibit dipolar dominated ¹³C DNP enhancements at 0.33 T, large scalar ¹³C DNP enhancements have been observed for chlorinated hydrocarbons (CCl₄, HCCl₃, H₂CCl₂). For example, both chloroform and chloroform-*d* exhibit L²IT ¹³C DNP

Figure 12 Carbon-13 L²IT DNP spectrum at 50 MHz for 1-chlorobutane 50% (v/v) in CCl₄/TEMPO (7.9×10^{-2} M). (Reproduced by permission from Dorn et al.⁷²)

Figure 13 (a) LC-¹³C DNP spectrum of chloroform (500 μ L sample; flow rate, 3.5 mL min⁻¹; number of scans per file, 31; file interval, 31 s; mobile phase, CCl₄). (b) LC-¹³C NMR spectrum of chloroform under the same conditions as the DNP experiment but without microwave power ($B_{1e} = 0$)

enhancements (with TEMPO) of +2200 and +2100, respectively, which are close to the scalar limit ($A_{\infty} = +2600$) for the ¹³C nuclide.⁷¹ For the corresponding SLIT experiment with a SPIN sample, ¹³C DNP enhancement of +760 and +1100, respectively, were reported.⁷² It is noteworthy that the SLIT ¹³C DNP enhancement for chloroform-*d* is over 60 times the ¹³C NMR thermal Boltzmann magnetization at 4.7 T.

In favorable cases, it is possible to envision NMR applications where practical ¹³C DNP enhancements could be useful. As one example, direct coupling of liquid chromatography with ¹³C DNP detection (LC-¹³C DNP) could help alleviate the sensitivity constraints of LC-¹³C NMR, as discussed in Section 3.2. Recent work from our laboratory⁸² has described directly coupled liquid chromatography with continuous flow SLIT ¹³C DNP detection (LC-¹³C DNP). Shown in Figure 13 is the LC-¹³C DNP profile of a single injected component (chloroform) with carbon tetrachloride as the chromatographic solvent. Although this is a contrived example, no signals were detected in the corresponding flow ¹³C NMR (no microwave irradiation) experiment. With the SPIN samples used in this study, a ¹³C DNP enhancement of ~60 has been obtained in comparison with the static thermal ¹³C NMR Boltzmann magnetization at 4.7 T. Clearly, improvements in higher field superconducting magnet design, instrumentation, and other polarization transfer experiments could provide continued evolution of improvements in NMR signal enhancement into the next century.

1 INTRODUCTION

The NMR methods involving pulsed magnetic field gradients provide one of the most attractive techniques for studies of molecular transport in lipid membranes and lyotropic liquid crystalline systems. One of the most successful applications of pulsed field gradient (PFG) NMR is found in the field of complex liquids. In particular, this has been an invaluable tool in determining the structures of cubic liquid crystalline phases.¹ Almost two decades ago, the first lateral diffusion coefficient of an amphiphile in a lamellar liquid crystalline phase was measured directly with the PFG NMR method.² In recent years, the range of applications of NMR diffusion techniques has been growing rapidly, due to the great improvements in the NMR equipment for diffusion and NMR microscopy.³ We concentrate here on lyotropic liquid crystalline systems (Figure 1) containing membrane lipids or other amphiphilic molecules.

2 NMR MEASUREMENTS OF LIPID LATERAL DIFFUSION IN ORIENTED BILAYERS

The translational motion of lipids can be measured using the conventional NMR diffusion pulsed field gradient spin echo (PFG-SE) method for anisotropic liquid crystalline systems, if all static proton dipole–dipole interactions can be removed by some mechanical method. For studies of the lateral diffusion of lipids in a lamellar phase the removal of these interactions can be accomplished by a macroscopic alignment of the lamellae between, for example, glass plates.^{2,4,5} In lipid bilayers, provided that the translational diffusion rapidly leads to a zero average of all the static, intermolecular dipolar interactions, the dipolar Hamiltonian $\hat{\mathcal{H}}_D$ can be written^{6,7}

$$\hat{\mathcal{H}}_D = \sum_{i>j} \sum_p F_0^{(2)}(ij) D_{p0}^{(2)}(\Omega) \hat{A}_p^{(2)}(ij) \quad (1)$$

where

$$F_0^{(2)}(ij) = 2\gamma^2 r_{ij}^3 \overline{D_{00}^{(2)}(\Omega_{ij})} \quad (2)$$

where γ is the magnetogyric ratio, r_{ij} is the distance between the protons in an intramolecular proton pair ij , Ω_{ij} is the Eulerian angle between the proton–proton vector and the bilayer normal (the so-called ‘director’), and $\overline{D_{00}^{(2)}(\Omega_{ij})}$ is a Wigner rotation matrix element.⁸ The bar indicates averaging over all the fast motions. Likewise, $D_{p0}^{(2)}(\Omega)$ is a rotation matrix element, and Ω is the Eulerian angle between the bilayer director and the applied magnetic field $\mathbf{B}_0$. $\hat{A}_p^{(2)}(ij)$ is a component of an irreducible tensor operator of rank two operating on the nuclear spin coordinates. In a strong magnetic field only the term containing $\hat{A}_0^{(2)}(ij)$ affects the spectrum. $\hat{\mathcal{H}}_D$ for all the protons in the hydrocarbon chain can then be written

$$\hat{\mathcal{H}}_D = \frac{1}{2}(3 \cos^2 \theta - 1) \sum_{i>j} F_0^{(2)}(ij) \hat{A}_0^{(2)}(ij) \quad (3)$$

From equation (3) it is obvious that if the bilayer is macroscopically aligned and oriented at the so-called magic angle $\theta = 54.7^\circ$, then $\hat{\mathcal{H}}_D = 0$ and the static dipolar couplings are reduced. In the NMR experiment the diffusion is measured in the direction of the magnetic field gradient. For a lipid membrane or a lamellar phase the diffusion coefficient is orientation dependent and two constants D_L and $D_\perp$ describe the diffusion. D_L is the lateral diffusion coefficient for motion parallel with the membrane, and $D_\perp$ determines the diffusion perpendicular to the bilayer. The measured diffusion coefficient D for an oriented membrane system is then

$$D = D_L \sin^2 \theta + D_\perp \cos^2 \theta \quad (4)$$

for a lamellae oriented at the magic angle $\sin^2 \theta = \frac{2}{3}$. In lipid bilayers, $D_\perp$ should be orders of magnitude smaller than D_L and the second term in equation (4) can be neglected.

Early on, this method was used to determine the lateral diffusion coefficient of a phosphatidylcholine lipid in a lamellar phase^{2,4} and for potassium oleate⁵ (Table 1). One of the most annoying difficulties one was faced with in the first measurements of the lateral diffusion coefficient of lipids was the contribution from water protons to the spin echo signal, which results in a diffusion coefficient for the lipids which is too large. This problem can be solved by a careful exchange of all free protons for deuterium. For example, the lateral diffusion coefficient of a typical amphiphile-like sodium octanoate (C_7COONa) was measured² to be equal to $2.1 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ at 24°C .

The lateral diffusion coefficient is also affected⁹ by a change in the water content in the lamellar phase (Table 1). It was found that the lateral diffusion of dipalmitoylphosphatidylcholine (DPPC) increased by a factor of 2 for a change in the $^2\text{H}_2\text{O}$ content of 15 to 40 wt.%. Wu and Huang¹⁰ have calculated the change in the lateral diffusion as a function of the water content according to the theory of Brownian motion in thin sheets. They found that the dependence of phospholipid diffusion on hydration can be attributed primarily to the change in the bulk water mobility in the multilamellar phase.

Figure 1 Structure of the most common liquid crystalline phases that membrane lipids can form: (H_I) normal hexagonal phase; (L_α) lamellar phase; and (H_{II}) reversed hexagonal phase.⁹⁸ (I_I) A scaled model of a unit cell of a cubic phase structure built up of closed micelles.⁸³ (I_{II}) Schematic drawing of a bicontinuous cubic phase belonging to the space group $Im3m$ ¹

Recently, we reported on the effect of glycerol on the translational and rotational motions in aqueous lipid bilayers.¹¹ A continuous decrease in the lipid diffusion coefficient was observed upon increasing glycerol contents; thus, at room temperature $D = 12.6 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$ for an aqueous L_α phase, while $D = 1.9 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$ where all the water was displaced by glycerol. It was concluded that glycerol between the lipid bilayers affects the lipid diffusion due to changes in the viscosity in the interbilayer regions. This is also in accordance with the findings of Wu and Huang.¹⁰

As intuitively expected, the lateral diffusion coefficient depends on the hydrocarbon chain length, but the dependence is rather weak.^{2,9} On the other hand, a strong dependence on the translational motion is observed for different polar headgroups of the amphiphiles.² Thus, lysophosphatidylcholine (lyso-PC) diffuses somewhat more slowly than the corresponding PC, although the latter has two acyl chains and the lyso compound only one.^{12,13} The bulkier headgroup of the lyso-PC molecules most probably plays an important role for the lipid lateral diffusion. In studies^{14,15} of the lateral diffusion of the two dominant glucolipids in the bacterium *Acholeplasma laidlawii* it was found that the translational motion of dioleoyldiglucoacylglycerol (DGLcDAG) is about 10 times faster than it is in dioleoyl-PC (DOPC)¹⁶ (Table 1). This difference in the lateral diffusion coefficients can probably be ascribed to differences in the interactions in the polar headgroup region and the packing of the lipids in the bilayer.^{2,15} Addition of a monoglucolipid results¹⁴ in a decrease in the lipid lateral diffusion, which has been suggested to be due to hydrogen bonding between the polar headgroups.¹⁵ The theoretical models used in molecular dynamics simulations of the

lateral diffusion in lipid bilayers disregard the effect on the polar headgroup, and therefore the calculated diffusion coefficients are much larger than the measured ones. A value of the diffusion coefficient which is about an order of magnitude (or even more) too large is obtained.^{17–19} The reason for this discrepancy is that headgroup–headgroup interactions are essential for slowing down the diffusion process.

The effects of cholesterol on lipid membranes have been studied extensively with a number of spectroscopic methods. Cholesterol has been shown to have a condensing effect on many lipids in the lamellar phase, but it was not until recently that the ternary phase diagram of DPPC/cholesterol/water was presented.²⁰ As the cholesterol content in the lipid bilayer increases, two lamellar phases with different molecular ordering are formed. This unusual behavior has been explained by a theoretical model.²¹ The influence of cholesterol on the lipid lateral diffusion in various lamellar liquid crystalline phases has also been investigated (Table 1) by PFG NMR.^{9,16} ¹H NMR and bandshape simulations of phospholipid/water systems show that the addition of cholesterol to lipid bilayers in the gel phase induces a ‘super-Lorentzian’ ¹H NMR bandshape, which is a result of an enhanced lateral diffusion of the PC molecules.²² It can be inferred from Table 1 that the cholesterol concentration has a very small effect on the phospholipid diffusion in unsaturated lipid bilayers. This is in accordance with recent molecular dynamics simulations, where it was found that cholesterol does not have any significant effect on the lateral diffusion of the chains.¹⁸ On the other hand, cholesterol has a large influence on the molecular ordering in bilayers.^{16,23–25} Thus, cholesterol increases the molecular ordering in a bilayer, but the diffusional motion

is unaffected. In a study¹³ of the lipid lateral diffusion of a mixture of DOPC, dioleoylphosphatidylethanolamine (DOPE), and water, both lipids were found to have about the same D_L (5×10^{-12} m² s⁻¹) as DOPC bilayers.¹⁶

The diffusional motion for powder samples of a liquid crystalline phase have also been measured.^{26–28} To reduce the static dipole interactions, a combined multiple pulse homonuclear decoupling and multiple pulse gradient technique²⁶ has been used to determine the self-diffusion coefficient. By this method the diffusion of DPPC has been studied at 25 °C with 15 wt.% ²H₂O in the $L_{\beta'}$ gel phase and in the lamellar phase of potassium oleate in 30 wt.% ²H₂O. The D values obtained in this way are 1.6×10^{-14} and 1.3×10^{-12} m² s⁻¹, respectively. Here the lateral diffusion coefficient is not obtained directly,²⁹ but is some kind of an average value, since the microcrystallites in the mesophase are randomly oriented. In

such a measurement, the diffusion coefficient obtained is too small, compared with the local lateral diffusion. In an early study, Roberts²⁷ used the stimulated echo to determine the surfactant diffusion in the hexagonal and lamellar phases of potassium laurate/heavy water at 80 °C. Somewhat surprisingly he obtained a similar diffusion coefficient ($D_{\text{lamellar}} = 2.4 \times 10^{-10}$ m² s⁻¹ and $D_{\text{hexagonal}} = 2.3 \times 10^{-10}$ m² s⁻¹) for both phases, although there is a large difference in their structure.

By using pulsed field gradient double quantum spin echo decays the translational diffusion of dichloromethane dissolved in two thermotropic liquid crystals has been studied.³⁰ Diffusion constants of the solute were determined parallel and perpendicular to the magnetic field.

A method has been presented for simulating ³¹P NMR spectra from a lipid vesicle dispersion. Experimental spectra are obtained by the use of a DANTE pulse sequence.³¹ The

simulation was based on molecules with axially symmetric lineshapes undergoing lateral diffusion on a curved surface. By fitting a set of spectra for which the system is allowed to evolve for a variable time interval after the DANTE excitation, a lateral diffusion coefficient can be calculated from the measured correlation time. Köchy and Bayerl³² measured ^2H quadrupolar transverse relaxation times obtained with the Carr–Purcell–Meiboom–Gill (CPMG) pulse sequence on spherical phospholipid bilayers on a solid support. They took advantage of the fact that the CPMG sequence can progressively filter out contributions to the T_2 relaxation arising from motions, such as lateral diffusion, which are slow on the NMR timescale. For POPC supported bilayers they got $D = 4 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$ at 30°C , in good agreement with PFG NMR.¹⁶ An attempt to estimate the lipid lateral diffusion in phospholipid vesicles from ^{13}C spin–spin relaxation was less successful.³³ The authors used a very simple model to describe the spin relaxation, a model which is similar to the so-called ‘two-step model’.^{34–36} The lateral diffusion coefficient required to fit the values of T_2 is larger by almost two orders of magnitude than the values obtained with PFG NMR.

3 NMR MEASUREMENTS OF WATER AND ION DIFFUSION IN LIQUID CRYSTALS

Most of the investigations of water diffusion in lyotropic liquid crystalline systems have been conducted on powder samples. The intermolecular exchange of protons in the water molecule is rapid on the NMR timescale, and therefore the water signal is relatively sharp even for a nonoriented sample. When the diffusion coefficient is determined for a powder sample with the NMR technique, the resulting echo has contributions from lamellae of all orientations θ , and²⁹

$$S(t) = \int_{-1}^1 \exp \left\{ -\frac{2\tau}{T_2(\theta)} - \sin^2 \theta (\gamma g \delta)^2 D (\Delta - \delta/3) \right\} d \cos \theta \quad (5)$$

The first measurements of water diffusion coefficients in lamellar phases of a powder sample were performed by Blinc and co-workers.³⁷ However, the complications described by equation (5) were not considered in their determination of the water diffusion at different temperatures for a sample containing 70% sodium palmitate and 30% water. Assuming that the water molecules in lamellae oriented close to the magic angle make the major contribution to the spin echo, the measured diffusion coefficient should be multiplied²⁹ by $\frac{3}{2}$ to give $D_L = 8 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$. Water diffusion coefficients have, however, also been determined for oriented lamellar phases using both protons³⁸ and deuterium³⁹ pulsed field gradient NMR. Callaghan and co-workers³⁹ found that the diffusion coefficients of $^2\text{H}_2\text{O}$ parallel and perpendicular to the bilayer surface are $D_L = 1.7 \times 10^{-9}$ and $D_\perp = 5 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$. In this work they also reported the first solid echo PFG ^2H NMR experiment performed on a lamellar phase of potassium palmitate and water in the presence of quadrupole splittings.

In the lithium perfluorooctanoate/water system, self-diffusion coefficients are reported for water, lithium and perfluorooctanoate ions in the lamellar and viscous neat phases, as a function of temperature.³⁸ The difference between diffusion along the water layers and across the perfluorooctanoate bilayers was found to be small for both water and lithium ions.

The lithium ion diffusion coefficient was only a factor of 3 larger than that of the perfluorooctanoate amphiphile. The lithium diffusion coefficient has also been determined in a lamellar phase composed of octanoate, water and decanol.⁴⁰ It was found that the lithium ion diffusion in this lamellar phase is independent of the composition. This is due to a constant fraction of bound ions in accordance with the ion condensation model previously used to describe the ion binding in lyotropic liquid crystals.^{41,42} Recently, the PFG method was applied to estimate of the rates of ionophore-mediated transmembrane exchange of lithium ion in liposomes.⁴³ There was good agreement between the transmembrane exchange rate estimated from PFG and magnetization transfer ^7Li NMR experiments.

Water diffusion coefficients have been measured for powder samples in the two-component system of DPPC and water.²⁹ The diffusion coefficients were found to be 4–10 times smaller than the translational diffusion coefficient in bulk water, and essentially unaffected by changes in the phase structure.

Some recent investigations of the effect of the mesophase structure on the measured water diffusion coefficients have also been published.^{44,47}

4 LIPID LATERAL DIFFUSION IN CUBIC LIQUID CRYSTALLINE PHASES

Lipid translational diffusion coefficients have been determined for a large number of different lyotropic cubic phases (Table 2). There is a great deal of interest in the structure and the properties of membrane lipids, in particular the cubic and reversed hexagonal phases, since these lipid phase structures are believed to be involved in many biologically important membrane processes such as fusion^{48–50} and membrane lipid regulation.^{1,15,51–53} With X-ray diffraction methods^{54–57} the space group of the cubic structure can usually be obtained, but seldom is it possible to distinguish a bicontinuous structure from a structure consisting of closed micellar aggregates. The strength of the PFG NMR method is that it can discriminate between these two structures, since restricted motions in space can be easily observed.⁵⁸ The first PFG NMR study of amphiphile diffusion in a cubic phase was carried out by Charvolin and Rigny⁵⁹ for a soap system of potassium laurate which formed a cubic phase at 80°C ($D = 2 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$). Such a large diffusion coefficient is not compatible with closed aggregates. Conclusions about whether or not a cubic phase consists of closed aggregates are based on a comparison between lipid diffusion coefficients measured by PFG NMR for neighboring phases, with which the cubic phase is in equilibrium.^{2,4,60,61}

The apparent diffusion coefficients of cubic and lamellar phases can be qualitatively compared with a simple model.^{2,61,62} The restricted lipid diffusion within aggregates building up the cubic lattice can be described by a local diffusion tensor, $\mathbf{D}$, where the component representing restricted diffusion in a certain direction is set to zero. The measured diffusion coefficient D is then an average value of the local diffusion tensor:

$$D = \frac{1}{3} \overline{\text{Tr} \mathbf{D}} \quad (6)$$

where the bar denotes an average over all the sites in a unit cell of the liquid crystal. Depending on how many directions

Table 2 Lipid Diffusion Coefficients D for Some Cubic Liquid Crystalline Phases

Lipid system	Composition (wt.%)	Temperature (°C)	$D 10^{11}$ (m ² s ⁻¹)	Reference

Water	10.0	83	0.64	
		90	0.78	

are effectively available for the lipid diffusion as measured by PFG NMR, three possibilities can be distinguished:

1. For a cubic phase with closed micelles, the lipid diffusion is restricted in all three directions, all the diagonal elements in the tensor are equal to zero, and D is ideally equal to zero.
2. A cubic structure of connected, long, rod-like aggregates permits lipid diffusion in one direction (along the rod) with the diffusion coefficient $D_{\parallel}$, and

$$D = \frac{1}{3} \overline{\text{Tr} \mathbf{D}_{\text{rod}}} = \frac{1}{3} D_{\parallel} \quad (7)$$

3. For a cubic phase with bilayer units, the diffusion $D_{\text{L}}^{\text{cub}}$ can occur in two directions, and

$$D = \frac{2}{3} D_{\text{L}}^{\text{cub}} \quad (8)$$

Thus, it can be expected that the aggregate structure in the cubic phase will appreciably influence the magnitude of the measured diffusion coefficients. In particular, PFG NMR provides a convenient method for distinguishing between bicontinuous cubic phases and those having closed aggregates. According to the above equations it should also be possible to obtain a crude estimate of the geometry of the aggregates building up the cubic phase, by comparing diffusion coefficients of lipids in the lamellar and cubic phases. Such a comparison

assumes that the local environment of the molecules in the diffusing process is the same in the two phases.

For the comparison of diffusion coefficients of lipids and water in cubic phases, an attractive mathematical model based on a description of the cubic structure by periodic minimal surfaces can be used.^{1,63–66} Recently, Anderson and Wennerström⁶⁶ have presented numerical results for the geometric obstruction factor of self-diffusion in different bicontinuous, cubic microstructures. The lipid diffusion was modeled as a diffusion of a particle, confined to the polar–apolar dividing surface, with a constant diffusion coefficient D_0 . It was proven analytically that the effective diffusion coefficient for a particle diffusing over any minimal surface of cubic symmetry is exactly equal to $\frac{2}{3}D_0$.

4.1 Bicontinuous Cubic Phases

The most widely investigated bicontinuous cubic phases occur in the monooleoylglycerol (MO)/water system. An early X-ray diffraction and PFG NMR investigation of the lipids and water in this system suggested that the cubic phase structure was based on lamellar bilayer units.⁶² The simple model described above was applied. The results of the MO system were compared with those of the aerosol OT/water system. The cubic phase of the latter system was suggested to be built up of rod-like aggregates. Using equations (7) and (8), surprisingly good predictions were made of the aggregate shape in the cubic phases.

Table 3 Water and Lipid Diffusion in Cubic Phases of Monooleoylglycerol and Water⁷²

¹ H ₂ O ^a (wt.%)	Phase	$D_{\text{cub}}^{\text{water}}/D_0^{\text{b}}$	$D_{\text{cub}}^{\text{lipid}} \times 10^{12} (\text{m}^2 \text{s}^{-1})$	p_b	n

39.5	<i>Pn3m</i>	0.300	1.69	0.38	5.0

^a25 °C.^bMeasured water diffusion coefficient relative to that of pure water (see text).

The cubic phases of several monoglycerides exist over an extended water and temperature region in the phase diagrams.⁶⁷ These phases can dissolve substantial amounts of hydrophobic and amphiphilic molecules,^{68–71} as well as glycerol.¹¹ The relationship between the water diffusion coefficient in cubic phases and the MO and water contents has been investigated. The water diffusion coefficient $D_{\text{cub}}^{\text{water}}$ in a simple two-site model can be written⁷²

$$D_{\text{cub}}^{\text{water}} = p_b D_{\text{cub}}^{\text{lipid}} + (1 - p_b) \beta D_0 \quad (9)$$

where p_b is the fraction of bound water, $D_{\text{cub}}^{\text{lipid}}$ is the lipid diffusion coefficient in the cubic phase, β is the obstruction factor for the diffusion of unbound water in the cubic phase, and D_0 is the diffusion of bulk water. The association of water obtained from the application of this simple model (Table 3) should be taken as a quantification of the extent to which the surface of the aggregates affects the dynamic properties of water. The diffusion coefficient of water⁷² has a discontinuous increase at around 34% water, which harmonizes with the two-phase region between the *Ia3d* and *Pn3m* cubic structures.⁷³ The lipid diffusion was found to increase with increasing unsaturation of the acyl chains of the lipid, and it decreases when larger molecules such as cholesterol, gramicidin A, and lysooleoyl-PC are solubilized in the cubic phase. In a cubic liquid crystal of MO, DOPC, and water, the individual lipid diffusion coefficients can be determined simultaneously. The results obtained suggest that when probe techniques are used the choice of the probe itself may influence the measured lipid diffusion coefficient. Recently, we investigated the cubic phase of *N,N*-dimethyldodecylammonium oxide (DDAO) having a molar ratio of 97:3 between DDAO and gramicidin and 27 wt.% water. At 25 °C, and taking the diffusion coefficient of water as $D_{\text{water}} = 6.3 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$, the measured diffusion coefficients for the methyl groups of the polar headgroup and the terminal methyl group were $7 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$. The latter coefficient should be compared with the coefficient for the diffusion of DDAO in a cubic phase in the absence of gramicidin; the value is $10 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$, i.e. gramicidin causes quite a small obstruction effect.

Several membrane lipid–water systems give rise to freeze–fracture replicas of three-dimensional regular arrays of closely packed globular elements, often called ‘lipidic particles’.⁷⁴ These structural pictures have often been poorly classified, and they have been suggested to show closed lipid aggregates, such as reversed micelles. Investigations of some liquid crystalline phases, giving rise to the freeze–fractured replicas, with X-ray diffraction and PFG NMR indicate that they are: (1) cubic liquid-crystalline phases; and (2), with one

exception, bicontinuous cubic phases.¹³ There is a rather large accumulation of diffusion coefficients to verify the structure of bicontinuous cubic phases (Table 2).^{2,12,14,15,28,53,61,75–80}

4.2 Discontinuous Cubic Phases

Usually these cubic structures are located between the micellar solution and the H_I phase in the phase diagram.⁸¹ X-Ray diffraction showed that this structure belongs to the space group *P43n* or *Pm3n*. For a long time it was debated whether the structure consists of closed aggregates^{12,60,75,82–84} or of a network of connected rod-like micelles with enclosed spherical micelles.^{55,85} This debate is now settled,^{86,87} and it has been shown conclusively by PFG NMR (Table 2)^{83,84,88} that this cubic structure is discontinuous. From NMR lineshapes,⁸³ spin relaxation,^{89,90} and time-resolved quenched fluorescence^{84,91} it is concluded that the structure consists of slightly elongated, closed micelles (Figure 1). Recently, a cubic phase consisting of reversed micelles was established.⁹² The structure of this phase, which belongs to the space group *Fd3m*, and which is composed of DOPC and dioleoylglycerol or oleic acid and sodium oleate, was recently solved by means of low-resolution crystallography.⁹³ The structure consists of a complex packing of two types of quasi-spherical reversed micelles. PFG NMR has shown⁹⁴ for the cubic phase composed of DOPC and dioleoylglycerol that reversed micelles build up the structure. The diffusion coefficient of DOPC is very small, close to $10^{-13} \text{ m}^2 \text{ s}^{-1}$, while the diffusion of water and dioleoylglycerol are much more rapid [of the order of $10^{-11} \text{ m}^2 \text{ s}^{-1}$ (Figure 2)]. It was concluded⁹⁴ that the reversed micelles contain mainly DOPC and the dioleoylglycerol merely plays the role of a solvent.

5 LATERAL DIFFUSION IN OTHER NONLAMELLAR LIQUID CRYSTALS

The translational diffusion of all three components has been measured in the ternary system DOPC/water/dodecane,⁷⁸ where dodecane induces an H_{II} phase. From a comparison between diffusion coefficients, it was concluded that dodecane resides between the water cylinders in the H_{II} phase.

Some lyotropic mesophases, called ‘nematics’, orient spontaneously in a strong magnetic field. Utilizing ultraviolet (UV) linear dichroism on a solubilized chromophore and PFG NMR on a nematic phase containing potassium dodecanoate, it was shown that this phase is built up of long rod-like micelles.^{95,96}

Figure 2 Stacked plot of spectra with increasing strength of the pulsed field gradient in a diffusion experiment performed on the system DOPC/1,2-dioleoylglycerol/ $^2\text{H}_2\text{O}$ (25.44/59.57/14.99) at 42 °C. The two peaks marked in the figure correspond to (A) CH_3 groups of the choline headgroup, and (B) terminal CH_3 groups of DOPC and 1,2-dioleoylglycerol. The diffusion coefficient of A is estimated to be $3 \times 10^{-13} \text{ m}^2 \text{ s}^{-1}$, while B shows two diffusion coefficients of 0.3×10^{-12} and $15 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$

The translational diffusion coefficient of the amphiphile was obtained from an aligned sample oriented at the magic angle. The surfactant diffusion along the rod was found to be $D_L = 5 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ for potassium laurate and $D_L = 8 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$ for sodium decyl sulfate.⁹⁶ These values compare well with the lateral diffusion coefficients for the corresponding lamellar mesophases (Table 1). By means of the relationship $\langle x^2 \rangle = 2Dt$, the length can be estimated to be longer than 2000 nm.

1 INTRODUCTION

Over the past decade, NMR has made a significant impact in chemical engineering, where it is being extensively used for the non-invasive study of dispersion and flow in porous media. Now it is finding effective use in the study of the mechanical properties of complex fluids. At the heart of that development is the dual capacity of NMR to provide information at the microscopic level regarding molecular organization and dynamics, and at the macroscopic level regarding the local rate of fluid deformation. It is the combination of the various tools of NMR spectroscopy with those of NMR imaging, and velocimetry that makes this dualism possible.

1.1 Complex Fluids and Rheology

We tend to think of condensed matter as sub-dividing into the two basic phases of solid and liquid. When subjected to a stress a solid will deform by a fixed amount and store energy elastically whereas a liquid flows and dissipates energy continuously in viscous losses. But many interesting materials in their condensed phase possess both solid and liquid-like properties. These include polymer melts and solutions, lyotropic and thermotropic liquid crystals, micellar surfactant phases, colloidal suspensions and emulsions. Most biological fluids, most food materials and many fluids important in industrial processing or engineering applications exhibit such complexity. Complex fluids manifest both an elastic and a viscous response, and they generally possess ‘memory’, which means that the stress which they exhibit at any moment will depend on their history of prior deformation. They tend to exhibit non-linear mechanical behavior, which means that their mechanical properties may change as the deformation increases, an effect that is generally attributed to molecular reorganization. And they invariably possess a wide range of characteristic time scales, from the rapid (ps to ns) local Brownian motion of small molecules or molecular

segments, to the very slow (ms to s) motions associated with the reorganization or reorientation of large molecular assemblies or macromolecules. The study of the mechanical properties of complex fluids is known as ‘rheology’,¹ a name which derives from the Greek word ‘rheo’ which means ‘to flow’.

Traditionally, rheology was a subject concerned principally with mechanical properties. Recently however attention has focused on trying to determine the molecular basis of complex mechanical properties. If we can better understand this basis then we can better design desirable fluidic properties, we can better process modern materials based on polymers and organized molecular states, we can better produce foods of the right texture, and we can better understand how nature works, for example in the way synovial fluid protects our joints, or in the way a spider can extrude a protein silk whose strength surpasses that of steel.

The interest in the molecular-mechanical link has led to the amalgamation of a number of spectroscopic and rheological techniques in which a flow or deformation cell is incorporated within the spectrometer detection system. Examples include the use of neutron scattering,² light scattering,³ birefringence and dichroism techniques.^{4,5} The most recent addition, NMR, has provided a number of new and valuable features. For example, it can be used to study materials which are optically opaque. The imaging capability of NMR means that it can be used to measure local velocity profiles and molecular densities directly. The wide-ranging spectroscopic tools available to NMR also make it possible to measure molecular order and dynamics.

1.2 History of Rheo-NMR

The earliest suggestion of the use of NMR methods to measure rheological properties was by Martins et al., in 1986.⁶ These authors pointed out that physically reorienting a sample of a nematic liquid crystal inside the NMR magnet would lead to a slow evolution of the spectrum during subsequent director realignment, interpretation of which could yield information about rotational visco-elasticity. This first type of Rheo-NMR method was later applied by Goncalves et al.,⁷ who used proton NMR spectra to monitor the magnetic field reorientation of an initially aligned sample of a nematic polymer liquid crystal, following the sudden physical rotation. By carefully fitting these spectra, rotational (Leslie) viscosities were calculated along with elastic constants associated with defect formation.

In 1990, Nakatani, Polliks and Samulski⁸ described a quite different Rheo-NMR experiment in which the proton NMR spectrum of a polymer melt was investigated under shear. They acquired their signal from a 100 kD polydimethylsiloxane sample which was contained in the gap of a cone-and-plate cell located in the NMR electromagnet, and in which the cone was driven to produce a shear rate of 4 s^{-1} . In this experiment the proton NMR spectrum broadened under shear and slowly relaxed once shearing ceased. In 1991, another approach to Rheo-NMR was reported by Xia and Callaghan (1991)⁹ who showed that NMR microscopy could be used to measure shear-thinning effects in the semi-dilute solution of a high molecular weight polymer, in particular by observing the deviation from Poiseuille flow apparent when

the fluid was pumped through a narrow (700 μm diameter) pipe. Then, in 1994, Grabowski and Schmidt¹⁰ demonstrated the use of the deuterium quadrupole interaction to investigate molecular order in studying the alignment of nematic liquid crystalline directors under shear, finding the equilibrium angle in the competition between the magnetic torque and the shear. This type of experiment proved able to yield the ratio of specific Leslie viscosities to the magnetic anisotropy. A detailed review of the science of Rheo-NMR can be found in a recent chapter¹¹ in *Reports on Progress in Physics*. Here we will outline the basic principles, and give a few examples.

1.3 Heterogeneity and the Need for Spatial Localization

In rheological measurements a material is subject to deformation and the stress, $\sigma(t)$, is monitored as a function of the time dependent strain, $\gamma(t)$. Such measurements require the deformation of fluid under the influence of relative motion of the fluid with respect to containment surfaces, the source of the externally applied stress. A simple example is that of pipe flow, where a velocity gradient exists between the wall, at which the fluid is stationary, and the center of the pipe, at which the fluid velocity is a maximum. Alternatively, the fluid may be held in a cell whose containment surfaces themselves move, generally in rotation and under the influence of an externally applied torque. Typical geometries used for this purpose are the cone-and-plate cell, the concentric cylindrical Couette cell, and the four roll mill. A feature of all these systems is that the flow is heterogeneous, although in the case of the cone-and-plate, the stress, and hence the velocity gradient may be expected to be uniform. However, even where the stress is uniform, some classes of fluids will exhibit heterogeneous shearing.

One of the great advantages of NMR is that it may be used to image the velocity field within a rheological cell, thus providing non-invasive insight concerning the exact nature of deformational flow. The key to this approach is the use of NMR imaging, and in particular, imaging at microscopic resolution, since the containment cells are often of mm length scale. However, even where velocimetry is not the primary aim of the experiment, and one instead wishes to examine molecular properties via NMR spectroscopy, the heterogeneous nature of many flows dictate that one spatially localizes the acquired spectrum. In consequence the selective excitation or spectroscopic imaging methods of NMR microscopy¹² are demanded. Because of these factors, Rheo-NMR often requires a dual focus on NMR microscopy and NMR spectroscopy, the former giving insight at the mechanical length scale and the latter at the molecular length scale.

2 MICRO-IMAGING AND NMR VELOCIMETRY

2.1 Encoding for Position and Displacement

The basic principles governing NMR microscopy have been described in detail elsewhere.¹² A spin at position $\mathbf{r}$, in the presence of a magnetic field gradient, $\mathbf{G}$, will experience an additional local spin precession frequency, $\gamma\mathbf{G}\cdot\mathbf{r}$, thus acquiring a phase $\exp(i\mathbf{k}\cdot\mathbf{r})$, $\mathbf{k}$ being the reciprocal space dimension

conjugate to $\mathbf{r}$ and given by $\gamma\mathbf{G}t$, where t is the evolution time. The nuclear spin density can be reconstructed by acquiring the complete signal over some appropriate volume of $\mathbf{k}$ space and performing an inverse Fourier transformation, generally, in two dimensions using a plane of spins prepared by a frequency-selective excitation. The high spatial resolution needed for NMR microscopy depends on the use of large polarizing field ($\geq 5\text{ T}$), small receiver coils of high sensitivity and gradient coils capable of delivering in excess of 20 G cm^{-1} .

In order to image velocity we further encode the signal with a Pulsed Gradient Spin Echo (PGSE) pair.^{13,14} These pulses define a second wave vector domain, $\mathbf{q}$, and impart a phase shift to the spins which depends directly on the motion of their parent molecules. In particular a spin moving by $\mathbf{R} = \mathbf{r}' - \mathbf{r}$ over the time Δ between the PGSE pulse pair acquires a phase factor $\exp[i\mathbf{q}\cdot\mathbf{R}]$. This contrast factor means that the signal acquired is effectively modulated both in $\mathbf{k}$ - and $\mathbf{q}$ -space. Double inverse Fourier transformation of the signal with respect to both $\mathbf{k}$ and $\mathbf{q}$ returns the local spin density $\rho(\mathbf{r})$ as well as the function, $\overline{P}_s(\mathbf{R}, \Delta)$, which describes the ensemble distribution of molecular displacements for that location. Image analysis software¹⁴ can be used to automatically process these distributions, using the width to

Figure 1 NMR proton density image obtained at 60 MHz from a 1.9 mm ID capillary in which a surfactant solution is flowing. Also shown is a velocity map from the same capillary displayed as a stacked profile plot

estimate the rms Brownian motion $(2D_s\Delta)^{1/2}$ and the mean displacement to estimate the flow. In this manner maps of $D_s(\mathbf{r})$ and $v(\mathbf{r})$ may be constructed. While the method depends on steady state flow conditions in the sample (a typical image will take several minutes to acquire), it does have the advantage of returning accurate and precise velocity maps. The sensitivity of the method is very high, enabling velocity resolution on the order of $10\text{ }\mu\text{m s}^{-1}$. Figure 1 shows an image of the Poiseuille velocity field for fluid in laminar flow in a capillary.

2.2 Rheo-NMR Devices

Pipe flow methods, while suitable for fluids of low viscosity, have limited use for soft solids or highly viscous liquids where excessive pressure gradients may be needed to maintain the flow. Furthermore pipe flow suffers from the need to provide a sufficient volume of fluid to maintain an inlet reservoir. For viscous materials and for systems where only a small ($<1\text{ g}$) quantity of fluid is available, it is necessary to use containment cells such as the cone-and-plate, cylindrical Couette, four roll mill and bi-axial extension cell. Figure 2 shows examples of such cells which fit within the rf coils of an NMR micro-imaging probehead.¹⁵ All of these deformational flow devices can be driven by a drive shaft which sits in the bore of the magnet and which is turned by a stepper-motor gearbox assembly mounted above the magnet bore.

2.3 Spatially Localized Spectroscopy

In order to acquire an NMR spectrum from a selected region of a sample it is necessary to use one of two methods. In the first, known as spectroscopic imaging, the spectral property is independently encoded in an imaging experiment so that the spectrum can be reconstructed at every position. In the second, known as localized NMR spectroscopy, a frequency-selective RF pulse is applied in the presence of a magnetic

field gradient, so that only spins from a desired region of the sample participate in the NMR spectrum. The former approach is comprehensive but time consuming while the latter approach is the most efficient when the region from which the spectrum is desired is known in advance. Such localized spectroscopy is extensively used in biomedical magnetic resonance, where a wide variety of excitation methods are successfully employed.^{16,17} One very effective spatial localization method is the composite soft/hard pulse 'selective storage' proposed by Post et al.¹⁸ and first implemented by Aue et al.¹⁹ This so-called 'split-sinc selective storage' consists of a $\pi/2$ non-selective pulse sandwiched between the leading and trailing halves of a $\pi/2$ sinc pulse of opposite phase. The relevant pulse sequence is shown in Figure 3. One of the advantages of this approach is that the desired slice magnetization is stored along the z -axis for later recall, while undesired magnetization is destroyed, thus making the method suitable as a 'front end' on any NMR sequence of interest. One such sequence might be a standard imaging routine (Figure 3a), so that it is possible to inspect and direct the chosen slice as required. Another advantage is the desired spins spend very little time in the transverse plane during the excitation process and thus suffer little T_2 relaxation. The stored z -magnetization is subject only to the much less severe effects of longitudinal relaxation. An example of selective storage used for spectroscopy is shown in Figure 3(b) where a spin echo is used to encode in both the evolution (t_1) and acquisition (t_2) domains.

Figure 4 shows an application²⁰ of the selective storage sequence shown in Figure 3, in order to deliver magnetization from a selected slice across a cylindrical Couette cell. In the present instance, that magnetization is subsequently spatially encoding to produce the image shown. Having confirmed that this slice is as desired, the same excitation is then used as a precursor to a spectroscopy experiment in which the deuteron quadrupole interaction is measured. This experiment is discussed further in Section 3.3.

G_p , G_r and G_s are respectively the phase, read and slice gradients. The spoiler gradient shown here is applied along z , however it may equally be applied in any (or all) of the three orthogonal directions following the z -storage

3 APPLICATIONS OF RHEO-NMR

3.1 Heterogeneous Flow and Shear Banding

One important class of rheological measurement concerns the large strain response known as the ‘flow curve’ for which the stress is measured as a function of the rate of strain, $\dot{\gamma} = \partial\gamma/\partial t$, in a steady state shearing flow. Figure 5(a) shows examples of flow curves for different classes of materials, including Newtonian, shear thinning, shear thickening, and fluids exhibiting a yield stress.¹ The principal rheometric device for such measurement, the small angle cone-and-plate, is shown in Figure 5(b). In this device the stress is almost uniform, varying weakly as $\text{cosec}^4\theta$ between the bottom plate ($\theta = 90^\circ$) and the cone ($\theta = 90^\circ - \alpha$) where α is the cone angle, typically less than 10° . The strain rate $\dot{\gamma} = \partial v_x/\partial y$ is assumed to be highly uniform since both the cone tangential velocity, v_x , and the gap are proportion to the local radius.

One of the most significant contributions of Rheo-NMR has been to show that the uniform shear-rate assumption may be violated in the case of certain classes of fluids in which pathological flow properties are exhibited. Figure 6 shows velocity maps and associated shear-rate maps²¹ obtained for the wormlike surfactant system, cetylpyridinium chloride/sodium salicylate in water. While the velocity gradients show no deviation from uniformity at very low shear rates, above a certain critical value $\dot{\gamma}_c$ we observe a dramatic variation in the rate-of-strain across the 6° cone gap in which a very high shear

rate band exists at mid-gap (i.e., fixed angle $\theta \approx 90^\circ - \alpha/2$) and independent of radius.

This shear banding phenomena explains the plateau in the flow curve. In the reptation reaction model of Cates,²² the wormlike micelle system is predicted to exhibit a constitutive behavior as shown schematically in Figure 7 where the region of decreasing stress as the shear rate increases finds its origin in the reduction in entanglements as the worm chains align in the flow. This section of the flow curve is associated with unstable flow. Cates et al.²³ have suggested that because of the instability beyond the shear rate corresponding to the stress maximum, σ_c , in the schematic flow curve, separation of distinct shear bands may occur, in the manner of a first order phase separation. These bands will be associated with the intersections of a coexistence stress tie line with the upper and lower branches of the underlying flow curve and the proportions of each band will be as required to satisfy the average shear rate. That the NMR results are consistent with this picture is clear in Figure 8 where a series of profiles show that as the gap apparent shear rate is increased, the high shear rate band expands in width at approximately constant maximum shear rate rate.

Shear banding effects have apparently been seen in these materials via optical birefringence.^{24,25} Birefringence effects are associated with anisotropic molecular alignment²⁶ and, as a consequence, the flow instability of the wormlike micelles have been associated with the onset of molecular ordering. NMR is also capable of investigating order and alignment

(a)

(b)

Figure 4 (a) NMR image³⁶ obtained from protons at 300 MHz of a Couette cell containing the polymer PDMS in the 0.5 mm annular gap and (b) image of the same cell obtained following the selective storage sequence shown in Figure 3(a)

through utilizing inter-nuclear dipole interactions or nuclear quadrupole interactions. It is through the use of such spectroscopic approaches that Rheo-NMR holds the promise of further linking mechanical and molecular properties.

3.2 Nematic Ordering under Shear

By the use of deuterium labeling, it is possible to employ the deuterium quadrupole interaction to measure local order, since this interaction results in a two line NMR spectrum in which the splitting is proportional to the local order parameter, and to the alignment with respect to the magnetic field via the second rank Legendre Polynomial, $P_2(\cos \theta) = (3 \cos^2 \theta - 1)/2$.

We have used quadrupole interaction spectroscopy, along with spectroscopic imaging, to investigate²⁷ shear banding in

a wormlike micelle system in which birefringence banding had been observed (20% CTAB/D₂O at 41 °C). Figure 9 shows the D₂O ²H NMR spectrum plotted as a function of radial position across the gap of a cylindrical Couette cell where the magnetic field is aligned with the vorticity axis. At the inner wall, where the stress is highest, a splitting is observed, indicative of a finite quadrupole interaction, while at the outer wall a single peak is observed. This data suggest the formation of a nematic phase at high stress and the transition to an isotropic phase, through a mixed phase region, at the region of low stress. What is particularly interesting about this experiment is that the associated velocity profile shows a banding in the shear rate which does not correlate simply with the local order parameters seen in the ²H NMR spectra, indicating that the molecular ordering is associated with the monotonically varying stress, rather than the discontinuously varying rate of strain. The example provides valuable new insight regarding the origin of shear banding in systems close to an isotropic/nematic phase transition.

3.3 Shear-induced Director Rotation

Nematic liquid crystals under shear stress experience not only deformational flow but also director reorientation.^{28–31} This process involves at least three independent rotational viscosities when describing the linear viscous response. In addition, the shear deformation results in the formation of complex defect structure which are governed by Frank elasticity effects³² associated with director splay bend and twist. This defect structure is crucial to any understanding of the non-linear visco-elasticity of liquid crystals. A nice description of the linear viscous response is given by the theoretical treatment of Leslie and Ericksen,^{28–31} who derived constitutive relations involving six independent coefficients, μ_n . In this theory the Frank elasticity is ignored. A detailed description of Leslie-Ericksen theory is beyond the scope of this review and can be found elsewhere.³³

In the context of Rheo-NMR, such nematic systems, which have intrinsic diamagnetic anisotropy, experience in addition a torque due to the magnetic field. Thus any deformation in the director field due to externally applied stress results in a competitive reorientation process. Two types of experiment involving such have been reported. The first is that performed by Martins and co-workers,^{6,7} who rapidly rotated a sample of a nematic liquid crystal which had been previously aligned in the magnetic field. In a variety of experiments the subsequent relaxation of the director field back to equilibrium was monitored via the use of both proton and deuterium NMR. In the second type of experiment due to Schmidt and co-workers,^{10,34} a nematic system has been continuously sheared in a cone-and-plate cell and the equilibrium direction orientation measured by use of the deuterium quadrupole interaction. The classes of material studied in this manner were thermotropic side-chain liquid crystal polymers, materials which present Leslie viscosities sufficiently large that significant alignment is possible at quite low shear rates, on the order of 1 s^{-1} . The rheometer used in these experiments incorporates a bottom plate which is free to rotate against a torsion spring, so that observation of the angular displacement gives a measure of the applied torque, and hence the stress applied to the fluid in the gap. As a consequence this Rheo-NMR device

Figure 5 (a) Schematic diagram of simple shear geometry and associated flow curves. (b) Cone-and-plate cell used to produce uniform stress and shear rate conditions along with the cone-and-plate Rheo-NMR device

allows additionally for simultaneous measurement for shear viscosity.

The steady-shear flow behavior of these nematic materials in the presence of a magnetic field, B_0 , is nicely described using the Leslie-Ericksen theory. Under a shear rate $\dot{\gamma}$ the director settles at an equilibrium angle to the magnetic field given by³⁴

$$\tan \theta = \mp \frac{\chi_a B_0^2}{2\mu_0 |\mu_3| \dot{\gamma}} \pm \sqrt{\left(\frac{\chi_a B_0^2}{2\mu_0 |\mu_3| \dot{\gamma}} \right)^2 \pm \frac{|\mu_2|}{|\mu_3|}} \quad (1)$$

where μ_2 and μ_3 are Leslie coefficients, and χ_a is the anisotropic part of the diamagnetic susceptibility tensor. The positive sign in the equation corresponds to a flow aligning ($\mu_2/\mu_3 > 0$) nematic while the negative to a tumbling ($\mu_2/\mu_3 < 0$) nematic. For a flow aligning system a stable angle is found for all shear rates, while for a tumbling nematic, a stable angle exists provided that $\dot{\gamma}$ is sufficiently small that the term inside the square root sign is positive.

Siebert et al. have demonstrated these effects in an experiment on two different nematic systems.³⁴ The ‘flow-aligning’ system was a nematic side-chain polysiloxane obtained

Figure 6 (a) Proton density image obtained at 300 MHz for cetylpyridinium chloride/NaSal wormlike micelle solution in a 7° cone-and-plate cell (horizontal field of view 25 mm with vertical magnification expanded by a factor of 6). Data taken from Reference²¹. (b) Stacked profile plot showing velocity distribution across the gap at an apparent shear rate of 1.5 s^{-1} . (c) As for (b) but for 16 s^{-1} . (d) Image of shear rate distribution for cetylpyridinium chloride/NaSal wormlike micelle solution at an apparent shear rate, $\omega/\tan \alpha$ of 16 s^{-1} , well beyond the critical shear rate and in an unstable region of the flow curve. Experimental shear rate profiles are taken along a line of approximately fixed radius as shown

Figure 7 Schematic flow curve for a fluid exhibiting double-valued stress vs rate-of-strain behavior. In the phase separation model for shear banding,²³ $\dot{\gamma}_1$ and $\dot{\gamma}_2$ correspond to coexisting shear rates at a single stress value

by the addition of 2,3,5,6-tetradeuterio-4-methoxyphenyl-4'-butenyloxybenzoate to poly(hydrogen methyl siloxane), a material with a glass transition temperature of 4°C and a clearing point of 97°C . The experiment was performed at 75°C and deuterium NMR spectra were acquired at 46 MHz for a range of shear rates. These spectra are used to obtain the angle θ from the quadrupole splitting $\Delta\nu = AP_2(\cos \theta)$, the constant A being determined from the splitting at zero shear. The splittings form an asymptote with increasing shear rate at a θ value of around 70° . This angle, associated as it is with the dominance of mechanical torque over magnetic torque, corresponds to the alignment angle which would occur at all shear rates in the case of zero magnetic field.

The tumbling system was a mixture of 65% (w/w) poly{4-[4-(4-methoxyphenylazo)phenoxy]butylmethacrylate} in 4-tri-deuterio-methoxybenzoic acid-[4-*n*-hexoxyphenylester]. Corresponding spectra for three different temperatures were obtained in this system and, once again, a shear-rate dependent angle θ was found associated with the competition between

Figure 8 Measured shear rate profiles²¹ from for cetylpyridinium chloride/NaSal wormlike micelle solution along a line of approximately fixed radius (as shown in Figure 6) for the 7° cone-and-plate data of Figure 6, for 11 s⁻¹, 14 s⁻¹, 19 s⁻¹ and 36 s⁻¹

the magnetic and mechanical torques. At shear rates beyond $\theta \approx 50^\circ$, no splitting could be found, a result consistent with the onset of director tumbling.

Figure 10 shows the respective alignment angles as a function of shear rates along with fits to the data using equation (1). In the case of the two different materials, opposite signs for μ_2 and μ_3 were necessary in order to reproduce the observed curvature of the data, confirming the respective flow aligning and tumbling character of the different polymer liquid crystals.

3.4 Shear-induced Deformation in Polymers

3.4.1 Measurement of Segmental Alignment

Another intriguing correlation between shearing and molecular conformation has been investigated by Rheo-NMR. When a random coil polymer melt is subjected to shear, the polymer chain suffers a bi-axial deformation in which the principal axis of extension has a preferred orientation with respect to the hydrodynamic velocity direction.²⁶ The geometry is as indicated in Figure 11. As a result of the deformation, the chain entropy is reduced, leading to an increase in the Free Energy, the basis of the elastic response of the polymer melt.

The deformation may be usefully described by means of the averaged segmental alignment tensor²⁶

$$S_{\alpha\beta}(t) = \left\langle \int_0^L ds u_\alpha(s, t) u_\beta(s, t) - \frac{1}{3} \delta_{\alpha\beta} \right\rangle \quad (2)$$

where $\langle \dots \rangle$ represents the ensemble average and the integral is taken over the curvilinear path of $\mathbf{s}$ chain segments along the chain length L . In the Doi-Edwards formulation of entangled polymer dynamics^{26,35} the stress tensor $\sigma_{\alpha\beta}$ is

Figure 9 ²H NMR spectra obtained²⁷ at 46 MHz, from 20% w/w CTAB/D₂O (41 °C) at different positions across the annular gap of a cylindrical Couette cell and at an apparent shear rate of 20 s⁻¹. Near the inner wall, where the stress is highest, a quadruple splitting is observed, consistent with an ordered phase, while near the outer wall the single peak of an isotropic phase is seen. In between a mixed phase region exists

shown to be directly proportional to the average alignment tensor $S_{\alpha\beta}$. Where polymer segments are aligned so that $S_{\alpha\beta}$ is non-zero, other physical properties will be anisotropic as well. In particular the dielectric properties which determine the material refractive index will be affected, leading to the optical anisotropy known as birefringence. The correspondence of the stress tensor and the anisotropic part of the refractive index tensor is known as the ‘Stress-Optical Law’.

Kilfoil and Callaghan³⁶ have used deuterium nuclear magnetic resonance to measure the alignment tensor in a high molecular weight polymethylsiloxane (PDMS) melt, employing a small horizontal Couette cell (gap 0.5 mm) in which both the velocity axis element S_{xx} and the gradient element, S_{yy} of the alignment tensor can be projected along the magnetic field. In this work a small benzene probe molecule was placed as a dilute species near a polymer segment whose orientation $\mathbf{u}$ defines the local director. The tumbling probe molecule undergoes steric interactions with that segment and experience an anisotropic mean orientation. The probe will thus exhibit a scaled down quadrupole splitting associated with that local site

Figure 10 Director orientation, θ as a function of shear rate³⁴ for both flow aligning (solid squares) and tumbling (open squares 325 K, solid circles, 328 K and open circles 333 K) nematic polymers. (From Ref.³⁴)

via a ‘pseudo-nematic’ interaction⁵ and samples an ensemble average value for $P_2(\cos \theta)$ as it diffuses over the molecular dimensions.

NMR micro imaging¹² is used to view the PDMS to image the velocity distribution across the gap while the selective-storage localized-spectroscopy method of Figure 3 is used to excite a desired region of the sample for spectroscopy experiments during steady-state shear. Figure 12 shows the measured alignment tensor elements along with fits using the Doi-Edwards model, in which the hierarchy of molecular relaxation times is terminated by the tube disengagement process associated with reptation. Also shown are the selected regions in which either the velocity direction or the velocity gradient (shear axis) is parallel to B_0 . The selective excitation pulse sequence which we used has been specially devised to minimize exposure of selected nuclear spins to any relaxation. The best overall fit yields a tube disengagement time of 310 ms, a value which is consistent with the terminal relaxation rate obtained from mechanical measurements. We have also carried out this experiment³⁶ at fixed shear rate ($\dot{\gamma}\tau_d = 3.9$), varying the angle ϕ between the velocity direction X and the magnetic field direction through a number of prescribed angles. This was achieved by changing the orientation of the magnetic field gradient used in the precursor selective storage pulse. The angular dependence of the splitting is shown in

Figure 11 Schematic diagram of ‘horizontal Couette cell’ in which the vorticity axis is aligned transverse to the magnetic field. The angle between the local velocity direction and the magnetic field is given by ϕ . The angle between the principal axis of the molecular (1, 2, 3) frame and the velocity axis, X , is the so-called extinction angle χ . The lower right inset shows elements of the alignment tensor, $\dot{\gamma}\tau_d$

Figure 12 Deuterium quadrupole splittings, Δv , versus shear rate, obtained³⁶ from the spectra derived from a selected region of the horizontal Couette cell in which the velocity direction (solid circles) and gradient direction (open circles) are respectively parallel to the magnetic field. The lines are fits using the Doi-Edwards model in which the absolute splitting (vertical axis) is scaled to yield the pseudonematic order parameter and the horizontal axis is scaled to yield the tube disengagement time, τ_d . The best compromise fit corresponds to $\tau_d = 310$ ms. The images at the right hand side show the regions selected for spectral investigation

Figure 13, along with the curve calculated using Doi-Edwards theory. Again the agreement is excellent, and consistent with the molecular principal axis being aligned at 14.6 degrees to the velocity axis.

3.4.2 T_2 Effects in Entangled Polymers and Gels

Another approach to Rheo-NMR has been demonstrated in a study of relaxation time effects in semi-dilute polymer

Figure 13 Deuterium quadrupole splittings,³⁶ Δv , versus orientation angle, ϕ , at a fixed Deborah number of $\dot{\gamma}\tau_d = 3.9$. The solid line shows the predictions of the Doi-Edwards model. The images show the selected regions used to obtain $\phi = 0^\circ$, 45° and 90°

solutions. Callaghan and Gil³⁷ used ^1H spectroscopy to monitor T_2 relaxation at selected sites on high molecular weight polyacrylamide (PAA) in water, using a cylindrical Couette cell. In this work micro-imaging was employed so that spatially dependent NMR parameters could be imaged across the shearing annulus. Shear banded flow was observed, and a marked reduction in polymer proton T_2 values was found in the high shear region of the flow. Furthermore, the recovery of that T_2 on shear cessation was indicative of slow reorganizational dynamics, on the order of tens to hundreds of seconds. The observed T_2 recovery was found to be multi-exponential and the fast components correlated well with the terminal times measured from the steady state flow curve. Figure 14 shows the correlation of the shear banded flow and the relaxation time reduction while Figure 15 shows the recovery of the proton relaxation rate following shear cessation.

The relaxation effects have been interpreted as arising from a deformation of the entanglement tube, such that under strong shear a significant extension occurs along the velocity direction. In consequence, the curvilinear length around tube bends will increase, leading to a slower correlation time for the final orientational motional averaging step, and hence, a faster T_2 relaxation rate.

In another experiment Callaghan and Gil³⁸ measured proton T_2 relaxation in Carrageen gels under shear and have used changes in relaxation times to gain insight regarding intermolecular interactions responsible for gelation. T_2 relaxation is a particularly easy NMR parameter to measure and may be equally easily used as a contrast in spatially resolved experiments. In consequence

Figure 14 Corresponding velocity and T_2 profiles³⁷ of PAA/D₂O as a function of radial position across the Couette cell annulus. The velocity profile was obtained at 0.50 Hz. The T_2 profile with open circles is for zero shear and with closed circles for an inner cell rotation speed of 0.5 Hz. The horizontal scales of both velocity and T_2 profiles are identical

the use of T_2 perturbation as a probe of molecular conformational or organizational changes should prove a particularly useful tool in Rheo-NMR studies of complex fluids, and especially for those where changes occur sufficiently slowly that the T_2 change can be observed as a transient.

3.5 Shear-induced Mesophase Structure

The potential for Rheo-NMR studies of shear-induced structure is considerable. One set of systems where NMR is ideally suited is that of lyotropic liquid crystalline phases. A range of cone and plate and cylindrical Couette cell studies have been reported by Lukashek et al.^{39,40} and Müller et al.⁴¹ These include cone-and-plate shearing of the hexagonal phase of the amphiphilic oligomer pentaoxyethylene monodecylether

(C₁₂E₅ in D₂O). Again, deuterium NMR quadrupolar splittings were used to give orientational information. The system appears to behave like a deformable solid, the final state at large strains corresponding to alignment of the hexagonal cylinders along the velocity axis.

For lamellar mesophases, a rich variety of structures is revealed by deuterium NMR studies under shear. For example in lamellar C₁₂E₄ shear-aligned, defect-laden lamellae with directors perpendicular to the velocity direction form at low shear rates, but with a transition to spherical multi-lamellar vesicles taking place at higher shear rates. A wide range of lyotropic phases under shear have been studied using neutron scattering and X-ray scattering. NMR provides an opportunity to probe quite different length and time scales in these systems and should prove an important tool in elucidating the effect of deformational flow on molecular organization and dynamics.

Figure 15 Recovery of the spin echo signal³⁷ obtained at a fixed delay $2\tau = 10$ ms for the CH/CH₂ region (solid circles) of the 300 MHz proton spectrum in 10% polyacrylamide in D₂O. The open circles show the equilibrium baseline echo intensity obtained some minutes later after full relaxation. The behavior of the water (HDO) peak is shown. This exhibits a much weaker, but observable, transient effect, probably due to baseline effects arising from neighboring polymer proton resonances

3.6 Perturbing Intermolecular Interactions

Central to an understanding of the tertiary structure of biological macromolecules is the role of intermolecular interactions such as hydrogen bonds. Under shearing flow, molecules on differing local streamlines are separated, at a scale-independent rate given by $\dot{\gamma}$. If this rate exceeds the characteristic rate at which intermolecular bonds are naturally broken and reformed, then the tertiary structure is disrupted and the moieties responsible for bond formation will exhibit quite different dynamics than in the bonded state. Thus, Rheo-NMR provides a means of determining which sites on a molecule are responsible for intermolecular binding, by simply comparing high resolution NMR spectra obtained in states of equilibrium and under shear. An example a study of from the synovial fluid polysaccharide, hyaluronin,⁴² where ¹³C spectra have been compared. The one site which shows a significant change is that of the acetamido carbonyl, a moiety which is believed to be responsible for inter-molecular hydrogen bonding.

This last experiment makes clear the very general capability of the Rheo-NMR method. With the exception of the loss of sample space due to the presence of the central cylinder, no sacrifice in signal-to-noise ratio is made in order to carry out NMR under a shearing flow. The use of the cylindrical Couette cell, with all its faces (within the rf coil) machined parallel to the B_0 field means that high spectral resolution is perfectly achievable. Consequently nearly all NMR spectroscopies that are possible in equilibrium, also are also possible under shear and this opens the way for a wide ranging series of NMR studies in which molecular sites responsible for intermolecular interactions are identified and their reaction dynamics determined.

3.7 Extensional Flow

Many important processes involving deformation of soft materials concern extensional flow. An example of an extensional flow cell is shown in Figure 16. The driving unit for this cell is programmed to move the top plug down and stop once the two plugs make contact, or, when a sample is present, when the sample has been deformed completely so as to fill the available volume. This action results in an increasing rate-of-strain, $\dot{\epsilon}$, as the two cylinders approach one another at velocity v , i.e.,

$$\dot{\epsilon} = \frac{v}{d_0 - vt} \quad (3)$$

where d_0 is the gap at the time origin, chosen to be the point at which both surfaces come into contact with the material to be deformed. If we take the vertical (compression) axis as z , then the deformation tensor is diagonal and the flow may be ideally described by²⁶

$$v_x = \frac{1}{2}\dot{\epsilon} \quad v_y = \frac{1}{2}\dot{\epsilon} \quad v_z = -\dot{\epsilon} \quad (4)$$

The sample generally takes the form of a semi-spherical blob of material. As a result, the final spacing of the plugs is determined by the point at which the material has spread to fill the available plug diameter. This device has been used to study the perturbation experienced in the proton spectrum of a polymer under deformation.⁴³

4 CONCLUSIONS

These examples provide a glimpse of possible applications of Nuclear Magnetic Resonance to the study of complex fluid

Figure 16 Schematic diagram⁴³ of extensional flow cell with plug diameter 16 mm

rheology. While this is a very new field of research in which only a handful of groups presently participate, the potential exists for a substantial increase in Rheo-NMR research activity. Systems studied to date include polymer melts and semidilute solutions, thermotropic and lyotropic liquid crystals and liquid crystalline polymers, micellar solutions, food materials and colloidal suspensions. Rheo-NMR suffers in a number of respects by comparison with optical methods. NMR is an expensive and complex form of spectroscopy which requires familiarity with the nuclear spin Hamiltonian and the associated effects of spin dynamics. It often suffers from poor signal-to-noise ratios and requires careful tradeoffs in parameter space in order to optimize its effectiveness. Nonetheless NMR offers some unique advantages, including the ability to work with opaque materials, the ability to combine velocimetry with localized spectroscopy, and the ability to access a wide range of molecular properties relating to organization, orientation and dynamics. Rheo-NMR has been able to provide a direct window on a variety of behaviors, including slip, shear-thinning, shear banding, yield stress behavior, nematic director alignment and shear-induced mesophase reorganization. The unique information available with this method suggests that it is likely to become an important tool in elucidating the intriguing rheological behavior of a wide range of complex fluids.

1 INTRODUCTION

In principle, accurate interatomic distances can be evaluated from careful analysis of specific dipolar interactions that were normally sacrificed under the condition of high power decoupling and magic angle spinning (MAS) techniques. A number of methods to recouple a single pair of dipolar interaction among homo and hetero nuclear spin pairs under the magic angle spinning condition have been proposed for determining the interatomic distances.^{1–10} These distances have been used as constraints to determine the three-dimensional (3D) structure of peptides and proteins.^{11–16} Rotational Echo DOuble Resonance (REDOR) was explored to recouple the relatively weak heteronuclear dipolar interactions under the MAS condition by applying a π pulse synchronously with the rotor period.^{8,9} Consequently, the transverse magnetization cannot be refocused completely at the end of the rotor cycle, leading to a reduction of the echo amplitude. The extent of the reduction of the echo amplitude as a function of the number of rotor periods depends on the strength of the heteronuclear dipolar interaction. This method is extensively used to determine the relatively remote interatomic distance of 2–8 Å. When a number of isolated pairs are involved in a REDOR dephasing,

the REDOR transformation could be useful in determining interatomic distances because it yields single peaks against distance axis for each heteronuclear coupling strength.^{17,18} This approach is, however, not applicable for the case where the observed nuclei in REDOR are coupled with multiple nuclei.

It turned out that determination of accurate interatomic distances (± 0.1 Å) is a prerequisite to arrive at a unique 3D structure of peptides and proteins.^{15,16} It is emphasized that the distance measurement by REDOR is the only available means to satisfy this condition among the many kinds of proposed procedures mentioned above in view of the achieved accuracy and precision. Nevertheless, it is important to bear in mind that every possible effort to achieve the distance measurement with ultimate accuracy is essential to any possible applications. This is because any measurement based on the peak-intensity is susceptible to unexpected errors, which are not easy to check. After brief survey, tips to avoid this problem will be discussed in detail.

2 THEORETICAL BACKGROUND OF THE REDOR EXPERIMENT⁸

Transverse magnetization that precesses about the static magnetic field due to the dipolar interaction under the MAS condition moves back to the same direction at every rotor period because the integration of ω_D over one rotor period is zero. Consequently, the rotational echo signals are refocused at every rotor period. When a π pulse is applied to the I nucleus (Figure 1), which is coupled with the S nucleus, in one rotor period, this pulse plays a role to invert the precession direction of the magnetization of the observed S nucleus. Consequently, the magnetization vector of the S nucleus cannot move back to the same direction after one rotor period. Therefore the amplitude of the echo intensity decreases.

The extent of the reduction of the rotational echo amplitude yields the interatomic distances. To evaluate the REDOR echo amplitude theoretically, one has to consider the average precession frequency in the presence of the π pulse at the center of the rotor period over one rotor cycle as follows:

$$\begin{aligned} \overline{\omega_D(\alpha, \beta)} &= \pm \frac{1}{\text{Tr}} \left[\int_0^{\text{Tr}/2} \omega_D dt - \int_{\text{Tr}/2}^{\text{Tr}} \omega_D dt \right] \\ &= \pm \frac{D}{\pi} \sqrt{2} \sin 2\beta \sin \alpha \end{aligned} \quad (1)$$

Figure 1 Pulse sequence and timing chart of REDOR experiment

2 NUCLEAR INTERACTIONS

where α is the azimuthal angle and β is the polar angle defined by the internuclear vector with respect to the rotor axis. Therefore, the phase angle, $\Delta\Phi(\alpha, \beta)$ for the Nc rotor cycle can be given by

$$\Delta\Phi(\alpha, \beta) = \overline{\omega_D(\alpha, \beta)} NcTr \quad (2)$$

where Tr is the rotor period. Finally, the echo amplitude can be obtained by averaging over every orientations as follows

$$S_f = \frac{1}{4\pi} \int_{\alpha} \int_{\beta} \cos[\Delta\Phi(\alpha, \beta)] d\alpha \sin\beta d\beta \quad (3)$$

Therefore, the normalized echo difference, $\Delta S/S_0$, can be given by

$$\frac{\Delta S}{S_0} = \frac{S_0 - S_f}{S_0} = 1 - S_f \quad (4)$$

Experimentally, REDOR and full echo spectra are acquired for a variety of NcTr values and the respective REDOR (S_f) and full echo (S_0) amplitudes are evaluated.

3 ROTATIONAL ECHO AMPLITUDE CALCULATED BY THE DENSITY OPERATOR APPROACH¹⁵

The REDOR echo amplitude can be evaluated more rigorously by using density matrix operators and for the REDOR experiment. The time evolution of density operator, ρ_0 , under the heteronuclear dipolar interaction during one rotor period, can be considered by taking the pulse length into account. The average Hamiltonian in the rotating frame over one rotor period can be given by

$$\begin{aligned} \overline{\mathcal{H}} &= \frac{1}{Tr} \left[\overline{\mathcal{H}_1(t)\tau} + \overline{\mathcal{H}_2(t)\tau} + \overline{\mathcal{H}_3(t)\tau} \right] \\ &= \frac{D}{4\pi} \left\{ \sin^2\beta [\sin(2\alpha + \omega_r t_w) + \sin(2\alpha - \omega_r t_w) - 2\sin 2\alpha] \right. \\ &\quad - 2\sqrt{2}\sin 2\beta \left[\sin\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \sin\left(\alpha - \frac{1}{2}\omega_r t_w\right) + 2\sin 2\alpha \right] \\ &\quad - \sin^2\beta [\sin(2\alpha + \omega_r t_w) + \sin(2\alpha - \omega_r t_w)] \frac{4\omega_r^2 t_w^2}{4\omega_r^2 t_w^2 - \pi^2} \\ &\quad + \sqrt{2}\sin 2\beta \left[\sin\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \sin\left(\alpha - \frac{1}{2}\omega_r t_w\right) \right] \\ &\quad \times \frac{2\omega_r^2 t_w^2}{\omega_r^2 t_w^2 - \pi^2} \left. \right\} \hat{I}_Z \hat{S}_Z \\ &+ \frac{D}{4\pi} \left\{ \sin^2\beta [\cos(2\alpha + \omega_r t_w) + \cos(2\alpha - \omega_r t_w)] \right. \\ &\quad \times \frac{2\pi\omega_r t_w}{4\omega_r^2 t_w^2 - \pi^2} \\ &\quad - \sqrt{2}\sin 2\beta \left[\cos\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \cos\left(\alpha - \frac{1}{2}\omega_r t_w\right) \right] \\ &\quad \times \frac{2\pi\omega_r t_w}{\omega_r^2 t_w^2 - \pi^2} \left. \right\} \hat{I}_Z \hat{S}_Y \\ &= a\hat{I}_Z \hat{S}_Z + b\hat{I}_Z \hat{S}_Y \end{aligned} \quad (5)$$

where ω_r is the angular velocity of the rotor and t_w is the duration of π pulse. $\overline{\mathcal{H}_1(t)}$, $\overline{\mathcal{H}_2(t)}$, and $\overline{\mathcal{H}_3(t)}$ are the average Hamiltonians corresponding to the period shown in Figure 1. Pulse length, t_w , is also considered in the calculations for the analysis of the REDOR results. The density operator, ρ (Tr), at Tr after evolution under the average Hamiltonian can be calculated as

$$\rho(Tr) = \exp(-i\overline{\mathcal{H}}Tr)\rho_0\exp(i\overline{\mathcal{H}}Tr) \quad (6)$$

where ρ_0 is considered to be $\hat{I}_Y$ after the contact pulse. Then finally the transverse magnetization at Tr can be given by

$$\begin{aligned} \langle \hat{I}_Y(Tr) \rangle &= Tr\{\rho(Tr)\hat{I}_Y\} \\ &= \cos\left(\frac{1}{2}\sqrt{a^2 + b^2}Tr\right) \end{aligned} \quad (7)$$

Echo amplitude in the powder sample can be calculated by averaging over every orientation as follows

$$S_f = \frac{1}{4\pi} \int_{\alpha} \int_{\beta} \langle \hat{I}_Y(Tr) \rangle \sin\beta d\beta d\alpha \quad (8)$$

Therefore, the normalized echo difference, $\Delta S/S_0$, can be given by equation (4). When the length of t_w is zero, equation (7) can be simplified as follows:

$$\langle \hat{I}_Y(Tr) \rangle = \cos\left(\frac{D}{\pi}\sqrt{2}\sin 2\beta \sin \alpha Tr\right) \quad (9)$$

In this case, equation (8) is equivalent to equation (3) in the case of Nc = 1.

4 SEPARATION OF S-I DISTANCES FROM A S_m-I_n MULTIPLE SPIN SYSTEM

It should be taken into account that a spin system for a doubly labeled sample should be generally treated as a multiple spin system ($S-I_n$ system) as shown in Figure 2(a) in which S^* is the observed nuclei and the recoupling pulse is applied to the I^* nuclei. The ideal S-I system is available only when the doubly labeled preparation is infinitely diluted with unlabeled preparation. In contrast, uniformly and singly labeled preparations are treated as S_m-I_n and $S-I_n$ systems, respectively (Figure 2b,c), although S^* in the latter is S nuclei of natural abundance. For this reason, it is advisable to utilize a variety of isotopically doubly labeled samples in order to obtain respective interatomic distances, although it is too laborious to make so many kinds of preparations. In fact, we made six kinds of doubly labeled preparations to determine the 3D structure of the pentapeptide, Leu-enkephalin.¹⁶ In addition, it is essential to make certain that all such preparations take the same polymorphic structure, because crystalline peptides or proteins under consideration may take different kinds of polymorphs depending on condition for crystallization, pH, temperature, etc.^{15,16} The most convenient way to check this problem is to use the conformation-dependent ¹³C chemical shifts,

Figure 2 Schematic representation of multiple spin systems for (a) doubly labeled, (b) uniformly labeled and (c) singly labeled samples

which are very sensitive to the presence of such polymorphic structure.^{15,16,19}

In this connection, use of a uniformly labeled sample seems to be more attractive both for the sample preparation and also to avoid the problem of polymorphs.²⁰ This view turned out to be not always true, however, because separation of a particular $S-I$ interaction from S_m-I_n spin systems, consisting of many homo- and heteronuclear dipolar and scalar interactions, is not always as straightforward as anticipated. In practice, all of the following conditions should be taken into account to determine the accurate interatomic distances of a particular spin pair from the uniformly labeled samples. First, J coupling among the observed S nuclei should be removed to reduce the phase twist due to the coherent evolution by J coupling, when its magnitude is comparable to the dipolar coupling, as illustrated for uniformly [^{15}N , ^{13}C]-labeled ammonium L-glutamate monohydrate at $\text{NcTr} = 8$ ms (Figure 3).^{21,28} This phase twist can be removed by using a shaped pulse as a Z-filter instead of a π pulse at the center position of the REDOR evolution period.²¹ Second, the linewidths of individual signals might be broadened due to strong homonuclear dipolar interaction with neighboring S nuclei, which should be eliminated by homonuclear decoupling pulses.²² Thus, in the case of a uniformly labeled sample, combination of both homonuclear dipolar and scalar decoupling is required to simplify the S_m-I_n to $S-I_n$ spin system. Third, relatively shortened transverse relaxation times (T_2), due to residual dipolar interactions, reduce the

Figure 3 ^{13}C -REDOR and full echo spectra at $\text{NcTr} = 8$ ms for crystalline uniformly labeled ammonium [^{15}N]-L-glutamate monohydrate

transverse magnetization during the dipolar recoupling period in REDOR experiments. This makes it difficult to observe the REDOR effect for the nuclei with relatively long internuclear distances, because it is required to measure relatively long evolution times to observe slow dephasing of the REDOR signals. Fourth, REDOR factors against the dipolar evolution time should be analyzed using multiply coupled $S-I_n$ spin systems rather than an isolated two-spin system under the condition of homonuclear decoupling.^{23–26} Accordingly, the four kinds of obstacles mentioned above should be removed to determine a set of accurate interatomic distances simultaneously for a uniformly labeled sample.

Gullion et al.²⁷ proposed a θ -REDOR as an approach to determine the individual interatomic distance in a uniformly labeled sample by dividing $S-I_n$ spin system into ' n ' number of isolated $S-I$ two-spin systems. This makes the REDOR analysis simple and allows one to use the REDOR transformation to obtain the dipolar coupling frequencies of individual $S-I$ spin couplings, although this method is not always easy to apply for measurement of a relatively long interatomic distance. Alternatively, homonuclear and scalar interactions are completely removed when natural abundant ^{13}C REDOR experiments were performed.²⁸ This approach provides an excellent means to determine the interatomic distances for a number of isolated spin pairs simultaneously under condition of high resolution (Figure 2c). Further, it is emphasized that this approach is free from the problem of the above-mentioned shortened T_2 values due to homonuclear ^{13}C spin interactions. However, a multiple coupled spin system, $^{13}\text{C}-^{15}\text{N}_n$, has still to be explicitly considered, because the intermolecular dipolar interactions cannot be neglected for a small molecule. In practice, we have recently demonstrated that accurate interatomic distances can be determined by analyzing intramolecular and

intermolecular dipolar contributions based on root mean square deviation (RMSD) between the theoretically and experimentally obtained REDOR factors.²⁸

5 TIPS FOR OBTAINING ACCURATE INTERATOMIC DISTANCES BY REDOR EXPERIMENT

It is emphasized that determination of interatomic distances accurate to 0.1 Å is a prerequisite to arrive at a unique solution of the three-dimensional structure of peptides, proteins, etc. A careful evaluation of the following points are the most important steps to obtain reliable interatomic distances by the REDOR experiment, although they have not always been seriously taken into account in a number of papers so far published.

5.1 The Finite Pulse Length and Fluctuation of RF Power

This effect is experimentally observed and calculated using equation (8) as shown in Figure 4. The REDOR parameter, $\Delta S/S_0$, as measured for 20% [1-¹³C, ¹⁵N]Gly($r_{\text{CN}} = 2.48$ Å) is plotted for the lengths of the ¹⁵N π pulse of 13.0 μs for the experiment and 24.6 μs (chosen to satisfy 10% rotor cycle) as a function of NcTr with the calculated lines using the π pulse

Figure 4 ¹³C REDOR and full echo spectra of [1-¹³C, ¹⁵N]glycine as recorded by the rotor frequency of 4000 Hz and NcTr of 4 ms (a) and plots of the $\Delta S/S_0$ vs. NcTr (b). Solid and open circles denote the experimental points recorded using a ¹⁵N π -pulse of 13.0 and 24.6 μs , respectively. Solid, broken and dotted lines are calculated using the π -pulses of δ , 13.0 and 24.6 μs , respectively, together with the C–N interatomic distance of 2.48 Å¹⁵

length and finite lengths (13.0 and 24.6 μs) of the π pulse. It turns out, however, that the finite length of the ¹⁵N π pulse does not significantly affect the REDOR effect provided that the pulse length is less than 10% of the rotor cycle at the rotor frequency of 4000 Hz. This effect, however, should be seriously taken into account if fast MAS, e.g., 40 kHz is used.

For most spectrometers, it is difficult to be free from fluctuations of RF power during the acquisition of REDOR experiments. It is, therefore, critical that RF power be stabilized. If not, the π pulse will vary in length. Consequently, the REDOR factor is greatly decreased to yield relatively longer interatomic distances. Compensation of instability of such RF power, e.g., by approximate pulse sequence is, therefore, necessary to be free from long term fluctuations of amplifiers. xy-4 and xy-8 pulse sequences have been developed for this purpose. The xy-8 pulse is known to be the best sequence to compensate for the fluctuation of the RF power.²⁹

5.2 Contribution from Natural Abundance Nuclei

Since the early stages of the REDOR experiment, contributions from natural abundance nuclei have been seriously considered as a major source of error in the distance measurement.³⁰ It appears that the observed dipolar interaction can be modified by the presence of such neighboring naturally abundant nuclei. This effect was originally taken into account by simply calculating the $\Delta S/S_0$ value for two isolated pairs and adding proportionally to the natural abundant fraction.³⁰ Careful analysis of the three-spin system, however, indicates that this sort of simple addition of the fraction of the two-spin system may result in a serious overestimate of the natural abundance effect, to yield shorter distances.²³ The most accurate way to consider the natural abundance effect is, therefore, to treat the whole spin system as a three-spin system by taking into account the neighboring carbons in addition to the labeled pair. In practice, contributions from naturally abundant nuclei can be ignored for ¹³C REDOR but not for ¹⁵N REDOR, because the proportion of naturally abundant ¹³C nuclei is much higher than that of the ¹⁵N nuclei.²³

5.3 Sample Dilution

¹³C, ¹⁵N-doubly labeled samples are usually used in the REDOR experiment to determine the interatomic distances between the labeled nuclei. More importantly, the dipolar interaction with the labeled ¹⁵N nuclei for the neighboring molecules should be taken into account as an additional factor to contribute to the dipolar interaction of the observed pair under consideration. This contribution could be serious when the observed distance is quite remote, because there are many contributions from nearby nuclei. This effect can be completely removed by diluting the labeled sample with a sample of naturally abundant molecules.²³ The sensitivity of the signals, however, has to be sacrificed if one wants to remove the effect completely as the sample must be diluted to 1/49 so that the signal intensity is reduced by a factor roughly 0.02.¹¹ Instead, it is advised to evaluate the REDOR factors at the infinitely diluted condition by extrapolating the data by stepwise dilution of the sample (i.e., 60%, 30%, etc.) without losing sensitivity, because a linear relationship between the REDOR factor and the dilution is ascertained by a theoretical consideration.²³ Alternatively, the observed plots of $\Delta S/S_0$ values against the

corresponding NcTr values for the sample without dilution can be fitted by a theoretical curve obtained from the dipolar interactions among three-spin systems, although the accuracy is not always improved to the level of the dilution experiment.

5.4 T_2 Effect

The transverse magnetization of the REDOR experiment decays as a function of the ^1H decoupling field.^{31,32} Under appropriate conditions, molecular motion may interfere with dipolar decoupling. This occurs when molecular motion, if any, exists when the motional frequency is of the same order of magnitude as the decoupling field, and hence the transverse relaxation times (T_2) are significantly shortened. In fact, it was found that the T_2 values of the carbonyl carbons in crystalline Leu-enkephalin are relatively short because of the presence of backbone motion.³³ This is a serious problem for the REDOR experiment, especially for the long distance pairs, because the S/N ratio is significantly deteriorated. In this case, it is required to measure the ^{13}C REDOR signal under a sufficiently strong decoupling field to elongate the transverse relaxation times. It is also useful to perform measurements at low temperature so as to reduce the motional frequency. Note, however, that crystalline phase transitions might be associated together with the freezing of the solvent molecules. This effect has been observed in a variety of enkephalin samples.^{34,35}

5.5 RF Inhomogeneity and Confinement of the Sample within RF Coil

In the commercial spectrometer, the rotor is designed to allow the sample volume to be as large as possible in order to gain better sensitivity. Obviously, this arrangement causes H_1 inhomogeneity, which results in a broad distribution of the lengths of the 90° pulses. This problem is serious for the REDOR experiment in which a number of π pulses are applied. As a result, the pulse error can accumulate during the acquisition to give serious error in the measurements of internuclear distances. Particularly, the samples located at the top or bottom part of the sample rotor feel quite a weak RF field. This causes a great reduction of the REDOR factor for a sample that is filled all the way along the sample rotor.¹⁵ This effect should be seriously taken into account prior to experiments with a commercial spectrometer. It is, therefore, strongly recommended to fill the sample only in the central part of the coil just like a multiple pulse experiment to be able to acquire as accurate interatomic distances as possible in the REDOR experiment.

5.6 Standard Sample

All of the considerations mentioned above are essential to achieve accurate interatomic distances. Nevertheless, it is also possible that accuracy may deteriorate even if one of the conditions is not satisfied for every possible measurement. It is therefore advisable to determine the interatomic distances from a standard sample, in order to check that all the conditions are satisfied. More preferentially, use of two standard samples for short and long distances is recommended. In practice, it is recommended to use [$1\text{-}^{13}\text{C}$, ^{15}N]glycine as the former standard sample whose C–N interatomic distance is determined as 2.48 Å by a neutron diffraction study, and to check that all the instrumental conditions of a given spectrometer are satisfied prior to every new experiment. As a second standard sample for long distance, it is recommended to use [^{13}C , ^{15}N]N-acetyl-Pro-Gly-Phe (Table 1). This crystalline peptide is very stable with relatively long T_2 values, because it does not contain solvent molecules, and the presence of two polymorphic structures is well characterized.¹⁵

6 NATURAL ABUNDANCE ^{13}C REDOR EXPERIMENT²⁸

As mentioned already, it is impossible to obtain meaningful interatomic distances from a uniformly labeled sample as far as the standard REDOR procedure is concerned. Instead, the natural abundance REDOR experiment is more preferable as a means free from both homonuclear dipolar and scalar interactions (Figure 3). This approach provides the interatomic distances for a number of isolated spin pairs simultaneously under high resolution conditions. Further, this approach is free from the problem of the shortened T_2 values due to homonuclear ^{13}C spin interactions. Figure 5 shows the REDOR and full echo spectra of natural abundance ^{13}C nuclei of singly ^{15}N labeled crystalline ammonium [^{15}N]L-glutamate monohydrate (I) at NcTr = 8 ms, in contrast to the twisted spectra from the same sample uniformly labeled (Figure 3). The assignment of peaks to the C_β , C_γ , C_α , $\text{C}=\text{O}$ and C_δ carbon nuclei, from high to low field, is also shown in Figure 5. The $\text{C}=\text{O}$ (176.6 ppm) peak was distinguished from the C_δ (179.5 ppm) peak as a peak yielding a stronger REDOR effect as shown in Figure 5. Similarly, the peak at 56.0 ppm was assigned to the C_α carbon nucleus that give the strongest REDOR effect among the three aliphatic ^{13}C peaks. In a similar manner, the peak at 30.5 ppm showed a stronger REDOR effect compared

Table 1 C–N interatomic distances (Å) determined from REDOR experiments as compared with those by X-ray diffraction and MD¹⁵

Labeled peptides	Experimental			Calculated		
	REDOR	X-Ray		Energy-minimized ^a	MD	
	Orthorhombic	Orthorhombic	Monoclinic ^b		Orthorhombic	Monoclinic
I	3.24 ± 0.05 (3.43 ± 0.05) ^c	3.19	3.76	3.17	3.22 ± 0.10	3.63 ± 0.10
II	3.43 ± 0.05 (3.66 ± 0.05)	3.35	3.21	3.57	3.32 ± 0.10	3.33 ± 0.10
III	4.07 ± 0.05 (4.45 ± 0.05)	3.99	3.91	4.17	3.92 ± 0.10	3.83 ± 0.10

Figure 5 Naturally abundant ^{13}C -REDOR and full echo spectra at $\text{NcTr} = 8\text{ ms}$ with two different carrier frequencies for crystalline ammonium ^{15}N -L-glutamate monohydrate. Arrows indicate carrier frequency positions at the center of (a) $\text{C}=\text{O}$ and C_δ resonances; and (b) C_β and C_γ resonances

with that at 35.2 ppm. Thus, the peaks at 35.2 and 30.5 ppm were assigned to the C_γ and C_β carbon nuclei, respectively.

The interatomic C–N distances between ^{15}N and $^{13}\text{C}=\text{O}$, $^{13}\text{C}_\alpha$, $^{13}\text{C}_\beta$, $^{13}\text{C}_\gamma$, and $^{13}\text{C}_\delta$ carbon nuclei were determined with accuracy of 0.15 Å, after experimental conditions were carefully optimized. ^{13}C -REDOR factors for a three-spin system, $(\Delta S/S_0)_{\text{CN1N2}}$, and the sum of two isolated two-spin systems, $(\Delta S/S_0)^* = (\Delta S/S_0)_{\text{CN1}} + (\Delta S/S_0)_{\text{CN2}}$, were further evaluated by the REDOR measurements on isotopically diluted I in a controlled manner. Subsequently, the intramolecular and intermolecular C–N distances were separated by searching the minimum in the contour map of the root mean square deviation (RMSD) between the theoretically and experimentally obtained $(\Delta S/S_0)^*$ values against two interatomic distances, $r_{\text{C-N1}}$ and $r_{\text{C-N2}}$. When the intramolecular C–N distance ($r_{\text{C-N1}}$) of the particular carbon nucleus is substantially shorter than the intermolecular distance ($r_{\text{C-N2}}$), C–N distances between the molecule in question and the nearest neighboring molecules can also be obtained, although accuracy is inevitably deteriorated. On the other hand, it was difficult to determine the interatomic distances in the same molecule

when the intermolecular dipolar contribution is larger than the intramolecular one as in the case of the C_δ carbon nucleus.

7 ACCURACY LIMIT FOR REDOR STRUCTURE OF PEPTIDE AND PROTEINS

Naito et al.¹⁵ systematically applied this technique to elucidate the three-dimensional structure of *N*-acetyl-Pro-Gly-Phe. They proposed that the carbonyl carbon of the (*i*–1)th residue and the amino nitrogen of the (*i*+1)th residue should be labeled with ^{13}C and ^{15}N , respectively. Namely, $[1-^{13}\text{C}]\text{N-acetyl-Pro-}^{15}\text{N[Gly-Phe(I)]}$, $\text{N-acetyl-}[1-^{13}\text{C}]\text{Pro-Gly-}^{15}\text{N[Phe(II)]}$ and $[1-^{13}\text{C}]\text{N-acetyl-Pro-Gly-}^{15}\text{N[Phe(III)]}$ were synthesized and the resulting distances were determined to be 3.24 ± 0.05 , 3.43 ± 0.05 , and 4.07 ± 0.05 Å respectively, utilizing the REDOR factor obtained for the infinitely diluted state to prevent errors from the contributions of the neighboring labeled nuclei. No correction from the contribution of the naturally abundant nuclei turned out to be necessary. Surprisingly, these distances do not agree well with the values obtained from an X-ray diffraction study available when the initial part of this experiment was performed, showing the maximum discrepancy between them to be 0.5 Å.³⁶ This value seems to be much larger than the expected error as estimated from the precision of the REDOR experiment (± 0.05 Å). The reason why the discrepancy is unexpectedly larger was explained by the fact that the crystal (orthorhombic) used for the REDOR experiments is different from that used in the X-ray diffraction study (monoclinic). To check the accuracy of the REDOR experiment, an X-ray diffraction study was performed on the same crystals used for the REDOR experiment. It was found that the distances from the new crystalline polymorph (orthorhombic) agree well between REDOR and X-ray diffraction, within an accuracy of 0.05 Å as shown in Table 1.

Conformational maps based on the possible combinations of the torsion angles of the Pro and Gly residues are calculated on the basis of the distance constraints thus obtained. Further, the difference of the chemical shifts between the C_β and C_γ carbons of the Pro residues $\Delta\beta\gamma$ was used as a constraint to determine the ψ value (-13°).³⁷ The ϕ angle of the Pro residue is in many instances restricted to -75° which shows the minimum energy in the residue. Therefore, the torsion angles of the Pro residue are uniquely determined to be (-75° , -28°). Using these torsion angles, conformational maps were again calculated. Finally two pairs of torsion angles were selected as (-112° , 48°) and (-112° , -48°). Minimization by a molecular mechanics calculation yielded the structure of the β -turn I structure, as shown in Figure 6(a). It is found that the three-dimensional structure of this peptide is well reproduced by a molecular dynamics simulation by taking into account all of the intermolecular interactions in the crystals, although a molecular dynamics calculation treating *single* molecular system does not always yield a correct picture as illustrated in Figure 6(b), unless otherwise all the molecules in a unit cell are correctly taken into account.^{15,38}

Elucidation of the three dimensional structure of an opioid peptide Leu-enkephalin crystal, Tyr-Gly-Gly-Phe-Leu grown from MeOH/ H_2O mixed solvent was performed by the REDOR method alone.¹⁶ This seems to be an additional challenge for this technique to reveal the three-dimensional structure of more complicated systems. Six differently labeled

Figure 6 Optimized conformation of *N*-acetyl-Pro-Gly-Phe as obtained by the minimization of energy from the initial form as deduced from the REDOR experiment (a) and a snapshot of the conformation deduced by MD simulation in vacuo (at 100 K) (b)¹⁵

Leu-enkephaline molecules were synthesized and the resulting interatomic distances (Figure 7a) are accurately determined. It turns out, however, that an extremely careful experiment is required to avoid unexpected crystalline conversion among polymorphs either by dehydration from a tightly sealed rotor or a phase transition occurring at ambient temperature. In

principle, pressure under MAS may shift a temperature of phase transition to some extent, because centrifugal force is proportional to the square of the spinning frequency. No significant effect, however, has been noted so far as a sample is spun at relatively low frequency such as 2–4 kHz but care might be taken when rotor is spun at a frequency one order of magnitude high as in 40 kHz.

This may be the reason why final refinement of X-ray diffraction data was abandoned in spite of the pioneering X-ray diffraction data as to the similarity of the tertiary structure between this opioid peptide and morphine.³⁹ Therefore, it is necessary to check whether the six differently labeled samples are all in the same crystalline polymorph by means of the ^{13}C chemical shifts. Otherwise, meaningless data can be obtained without this precaution. When the distance data are converted to yield the necessary numbers of torsion angles, a unique combination of torsion angles in the corresponding conformational map is determined sequentially as shown in Figure 7(b). It is emphasized that accuracy within 0.1 Å is essential to select unique torsion angles for each amino acid residue. Namely, if the error is larger than 0.41 Å, torsion angles can no longer be selected as shown in Figure 8.

It is also important to point out that the chemical shift data can be used as additional constraints. A three dimensional structure was thus determined as shown in Figure 9. However, this structure is not the same as that previously determined

Figure 7 (a) Schematic representation between the sites of a variety of [^{13}C , ^{15}N]-doubly-labeled Leu-enkephalin dehydrates and their related torsion angles. (b) Block diagram to show how respective torsion angles are uniquely determined by the combined examinations of the conformation maps based on the distances of four-bonds apart (I, II, III and VI) and five-bonds apart (IV and V)¹⁶

Figure 8 Conformation maps for $(\Psi_{\text{Gly2}}, \omega_{\text{Gly2}})$ based on the interatomic distance of 4.55 Å with increased experimental errors: (a) ± 0.10 Å, (b) ± 0.20 Å, and (c) ± 0.41 Å¹⁶

by X-ray diffraction because one is dealing with a crystalline polymorph that is not fully explored. It is possible to figure out the molecular packing in the crystals by looking at the intermolecular dipolar contribution. Since the intermolecular dipolar contributions in I and III are larger than that of II, a β -sheet is formed as one peptide interacts with two peptides as an antiparallel β -sheet as shown in Figure 9(b).

Finally, it should be pointed out that, in order to isolate an S–I spin pair, it is essential to avoid any unnecessary errors from dipolar contributions of neighboring molecules from the overall S–I_n spin system. This is generally encountered for a variety of peptides and the aforementioned dilution procedure turned out to be not required in the case of α -helical polypeptides as far as the measurement of the interatomic distance for $^{15}\text{NH}(i) \cdots \text{O} = ^{13}\text{C}(i+4)$ is concerned.⁴⁰ This is because the interhelical dipolar contribution is found to be negligible in view of the mutual packing of α -helical chains or random mutual orientation between isotopically labeled atoms. Further, it was found that in helical peptides, due to the manner of chain packing, this kind of measurement is feasible to yield 4.5 ± 0.1 Å, without any assumptions, for a variety of transmembrane α -helical peptides in lipid bilayers to mimic a biomembrane at a temperature below liquid crystalline-gel phase transition at which rotation of such peptides about the α -helical axis turns out to be frozen, in spite of the presence

Figure 9 (a) Three-dimensional structure of Leu-enkephalin dihydrate determined uniquely by the successive application of the conformation maps as well as additional constraints of the conformation-dependent ^{13}C chemical shifts. (b) Three kinds of models for putative intermolecular packing as illustrated in the cartoons: (1) interaction through parallel β -sheet form; (2) interaction through an antiparallel β -sheet; and (3) interaction through interaction of three molecules. Solid and dotted arrows correspond with the dipolar interactions between intramolecular ^{13}C – ^{15}N pairs, respectively¹⁶

of rotational motions of lipid molecules, as viewed from the observation of three principal components of ^{13}C and ^{31}P chemical shift tensors.⁴¹ As is shown in this example, it is essential to ensure that molecular motion is reasonably ceased.

8 CONCLUSIONS

REDOR is one of the most powerful methods to determine accurate interatomic distances after taking into account a number of points in applying the method to a practical sample. Simultaneous measurement of interatomic distances using uniformly labeled samples can only be achieved by removing the homonuclear dipolar and scalar interactions. Alternatively, natural abundance ^{13}C REDOR measurements provide interatomic distances simultaneously free from homonuclear dipolar and scalar interactions. These accurate interatomic distances obtained from REDOR experiments can provide important information on structure and molecular packing of solid peptides and proteins.

1 INTRODUCTION

Transfer of spin order is of great importance in magnetic resonance and plays a crucial role in two-dimensional correlation spectroscopy, two-dimensional exchange spectroscopy, and for the sensitivity enhancement of low- γ nuclei. Well-known examples are Hartmann–Hahn cross polarization,^{1,2} spin diffusion,³ INEPT,⁴ and NOESY⁵ experiments.

All experiments mentioned above are ‘sudden’ experiments in the sense that they start with the preparation of an initial state characterized by a density operator which corresponds to a non-equilibrium state. Such a non-equilibrium state evolves under the transfer Hamiltonian. The time-evolution of the density operator leads to a transfer of spin order. In an adiabatic experiment, on the other hand, one starts with a density operator that does not evolve under the initial Hamiltonian. The time evolution is initiated by ‘slowly’ and continuously changing the Hamiltonian in the course of the spin-order transfer such that the density operator follows the Hamiltonian.

A simple example to illustrate the differences between sudden and adiabatic experiments is the inversion of the z -magnetization of a single spin 1/2. The ‘sudden’ version is a π -pulse applied on-resonance with a pulse duration of $\tau = \pi/\omega_1$. The behavior of the magnetization during the pulse is illustrated in Figure 1(a,c). Critical settings for obtaining perfect inversion are the resonance frequency (which must be ‘on-resonance’, i.e., $\omega_{\text{rf}} \approx \omega_0$) and the product of pulse length τ and rf-field strength ω_1 . The well-known oscillatory behavior of M_z as a function of the pulse length (Figure 1c) is typical for ‘sudden’ experiments. The adiabatic counterpart of such an inversion pulse is an adiabatic passage through resonance realized by a frequency sweep of the rf-irradiation frequency $\omega_{\text{rf}}(t)$. The behavior is illustrated in Figure 1(b,d). The inversion starts by irradiating the spin system with an

irradiation frequency $\omega_{\text{rf}}(0)$ much lower than the resonance frequency ω_0 and ends with a frequency $\omega_{\text{rf}}(\tau)$ much higher than ω_0 . The precise shape of the frequency sweep $\omega_{\text{rf}}(t)$ is only important if one is interested in minimizing the pulse length at a certain ‘degree of adiabaticity’. The Hamiltonian in the rotating frame (rotating with frequency ω_0 about the static magnetic field) is given by

$$\mathcal{H} = \chi(t)I_z + \omega_1 I_x \quad (1)$$

where $\chi(t) = \omega_{\text{rf}}(t) - \omega_0$ is the off-resonance term. As a function of the time t , the Hamiltonian is rotated from being parallel with I_z to being antiparallel with I_z . As long as the frequency sweep $\omega_{\text{rf}}(t)$ is slow enough (see below) and the sweep range is large enough ($|\omega_{\text{rf}}(0) - \omega_0| \gg |\omega_1|$ and $|\omega_{\text{rf}}(\tau) - \omega_0| \gg |\omega_1|$), the magnetization is inverted irrespective of the exact values of the resonance frequency ω_0 , the sweep length τ , and the rf-field strength ω_1 . It will become clear in the following, that the polarization transfer experiments of interest are also fully described, for two spin systems, by the simple picture of Figure 1. The polarization transfer will take place in a fictitious spin-1/2 subspace. The only difference to the inversion of z -magnetization will be the labelling of the axes.

In the absence of relaxation, the time evolution of a spin system always conserves the entropy and the total spin order. It is, therefore, in principle reversible and ‘adiabatic’ in a thermodynamical sense. This is obvious for the simple example of Figure 1 but has also been shown for polarization transfer processes in multi-spin systems for the case of spin diffusion^{6,7} and cross polarization.^{8,9} In the present context, we use the term adiabatic in a more restricted sense, namely for processes where in addition to the conservation of spin order, the density operator and the instantaneous Hamiltonian commute at all times,¹⁰ i.e.,

$$[\sigma(t), \mathcal{H}(t)] = 0 \quad (2)$$

In this chapter, we will treat the transfer of polarization or longitudinal magnetization between two spins. We start with z -magnetization on a source spin (spin 1) as described by a density operator of the form $\sigma(0) = cI_{1z}$ and measure the amount of polarization on the destination spin (spin 2) after the transfer. The final density operator is of the form $\sigma(\tau) = c'(\tau)I_{2z} + Z(\tau)$ and we can abbreviate the transfer as $I_{1z} \rightarrow I_{2z}$. Here $Z(\tau)$ describes the part of the density operator orthogonal to I_{2z} . We define the polarization P_k of spin k as the expectation value of the operator I_{kz} . The polarization is related to the longitudinal magnetization by $M_{kz} = N_k \hbar \gamma_k P_k$. In general, neither the magnetization nor the polarization of the entire spin system are conserved quantities,¹¹ but there is an important class of experiments where the sum polarization $\sum_k P_k$ is conserved. Therefore, we will discuss the experiments always in terms of polarization.

Polarization transfer is a special form of the more general term spin-order transfer. Other examples of spin-order transfer include coherence transfer, e.g., $I_{1x} \rightarrow I_{2x}$, and transfer of coherences to two-spin order terms, e.g., $I_{1x} \rightarrow 2I_{1y}I_{2z}$. The distinction between polarization and coherence depends on the frame of reference and is not always unique.

Figure 1 Schematic comparison of (a) sudden and (b) adiabatic inversion of the z -component of the magnetization vector. In the sudden case a π pulse is applied while in the adiabatic case a frequency sweep is shown. The time evolution of the z -magnetization as a function of the pulse duration τ is shown in (c) and (d) for sudden and adiabatic schemes, respectively. For the sudden experiment, the precise choice of τ is crucial to obtain efficient inversion; for adiabatic experiments a variation within rather wide limits does not lead to significant changes in inversion efficiency

Polarization transfer between two spins can often be described by a fictitious spin-1/2 system.^{12,13} This is a consequence of the structure of the dipolar-coupling interaction, which has a matrix representation in the product base $|\alpha\alpha\rangle, |\alpha\beta\rangle, |\beta\alpha\rangle, |\beta\beta\rangle$ of the form

$$\frac{1}{2} \begin{bmatrix} \xi^\Sigma & 0 & 0 & d^\Sigma \\ 0 & \xi^\Delta & d^\Delta & 0 \\ 0 & d^\Delta & \xi^\Delta & 0 \\ d^\Sigma & 0 & 0 & \xi^\Sigma \end{bmatrix} \quad (3)$$

There are no coupling elements between the sum-polarization subspace spanned by $|\alpha\alpha\rangle, |\beta\beta\rangle$ and the difference polarization subspace spanned by $|\alpha\beta\rangle, |\beta\alpha\rangle$. The scalar J -coupling Hamiltonian has the same basic structure. If, besides the dipolar interaction, only a 'Zeeman-type' interaction of the form

$$\frac{1}{2} \begin{bmatrix} \chi^\Sigma & 0 & 0 & 0 \\ 0 & \chi^\Delta & 0 & 0 \\ 0 & 0 & -\chi^\Delta & 0 \\ 0 & 0 & 0 & -\chi^\Sigma \end{bmatrix} \quad (4)$$

is present, the total Hamiltonian can be written as the sum of two fictitious spin-1/2 Hamiltonians

$$\mathcal{H} = \mathcal{H}^\Sigma \oplus \mathcal{H}^\Delta \quad (5)$$

with

$$\mathcal{H}^\kappa = \chi^\kappa \cdot S_z^\kappa + d^\kappa \cdot S_x^\kappa + \frac{1}{2} \xi^\kappa \cdot 1I^\kappa \quad (6)$$

where κ stands for either Σ (the double-quantum subspace) or Δ (the zero-quantum subspace) and $1I^\kappa$ is the identity operator in the considered subspace. The symbol ' $\oplus$ ' emphasizes that we take the direct sum of the two subspaces of dimension 2×2 . Not considering the term proportional to the identity operator which does not influence the evolution of the density operator in the subspace κ , the Hamiltonian

$$\mathcal{H}^\kappa = \chi^\kappa \cdot S_z^\kappa + d^\kappa \cdot S_x^\kappa \quad (7)$$

has the same form as the one of equation (1) with the dipolar amplitude coupling element d^κ taking the role of the rf field in equation (1). The separation into a sum and difference subspace can also be applied to the density operator σ , given that $\sigma(0)$ can be divided according to

$$\sigma = \sigma^\Sigma \oplus \sigma^\Delta \quad (8)$$

If the density operator contains only terms proportional to I_z , such a separation is always possible according to

$$\sigma = p_1 I_{1z} + p_2 I_{2z} = p^\Sigma I_z^\Sigma + p^\Delta I_z^\Delta \quad (9)$$

with $p^\Sigma = p_1 + p_2$, $p^\Delta = p_1 - p_2$, $I_z^\Sigma = 1/2(I_{1z} + I_{2z})$, and $I_z^\Delta = 1/2(I_{1z} - I_{2z})$. Obviously, the inversion of the difference polarization $I_z^\Delta \rightarrow -I_z^\Delta$ is equivalent to a complete polarization transfer, i.e., $I_{1z} \rightarrow I_{2z}$ while the inversion of the sum magnetization $I_z^\Sigma \rightarrow -I_z^\Sigma$ leads to the polarization transfer $I_{1z} \rightarrow -I_{2z}$.

In polarization transfer schemes based on the dipolar coupling, the value of the effective dipolar coupling constant d^k depends on one or two of the three Euler angles which describe the orientation of the crystallite in the rotor-fixed frame. For a powder sample, the resulting distribution of effective dipolar coupling frequencies does not allow a complete polarization inversion by the equivalent of a 180° pulse with $\tau \cdot d^k = \pi$. An optimum choice of the pulse length τ leads to a maximum transfer efficiency for such a ‘sudden’ experiment of 73% and to an equilibrium value of 50% in an isolated two-spin system. For adiabatic methods, the maximum transfer efficiency is still 100% even in a powder sample. It will be shown below, that adiabatic polarization transfer schemes show a greatly reduced sensitivity to rf-field inhomogeneities compared to their sudden equivalent.

If the adiabaticity is violated during the sweep, the density operator and the Hamiltonian do not commute at all times during the polarization-transfer process ($[\mathcal{H}(t), \sigma(t)] \neq 0$). Under this condition, the density operator starts to precess around the Hamiltonian. Such a precession will be damped by relaxation and possibly rf-field inhomogeneities and lead to a reduction in transfer efficiency.

A number of adiabatic heteronuclear polarization transfer methods have been introduced starting with the ADRF-ARRF scheme for static samples^{2,14,15} and the static adiabatic passage through the Hartmann–Hahn matching condition.¹⁶ Adiabatic passage Hartmann–Hahn cross polarization (APHH CP) can also be applied under MAS.^{17–21} In these experiments, the amplitude difference of the two applied rf-fields $\omega_{1I}(t) - \omega_{1S}(t)$ is the parameter $\chi(t)$ which is varied in an adiabatic fashion around the Hartmann–Hahn matching condition, i.e., $\chi(t) = \omega_{1I}(t) - \omega_{1S}(t) - f \cdot \omega_r$ with $f = \pm 1, \pm 2$. The variation can also take place around the original Hartmann–Hahn condition with $f = 0$ if the adiabatic transfer is combined with multiple-pulse irradiation.²²

There is also a number of homonuclear adiabatic polarization transfer schemes under MAS. In adiabatic passage rotational resonance (APRR)²³ the spinning frequency of the MAS rotor $\omega_r(t)$ is varied to obtain a sweep through the rotational resonance condition^{24–26} $\Omega_1 - \Omega_2 = n\omega_r$ with $n = \pm 1, \pm 2$ and Ω_k being the isotropic chemical shift of spin k . This leads to the definition $\chi(t) = \Omega_1 - \Omega_2 - n\omega_r(t)$. Adiabatic passage RR was also applied to the central transition of half-integer quadrupolar spins where conventional RR cannot be applied due to the broadening of the resonances by second-order quadrupolar terms.²⁷ A variation of APRR is the rotational resonance tickling experiment^{28–30} where the RR experiment is carried out in a tilted rotating frame and the sweep is accomplished at constant MAS frequency by changing the amplitude of the applied rf-field.

In the adiabatic version of the homonuclear rotary-resonance (HORROR) experiment³¹ called dipolar recoupling enhancement through amplitude modulation (DREAM)^{32,33} the amplitude of the applied rf-field $\omega_1(t)$ is varied as a function of time to obtain an adiabatic sweep through the HORROR recoupling condition $n \cdot \omega_1 = \omega_r$ with $n = \pm 1, \pm 2$ leading

to $\chi(t) = \omega_r - n \cdot \omega_1(t)$. Recently a rf-field-driven dipolar recoupling scheme for half-integer quadrupolar nuclei was introduced³⁴ which can also be implemented in an adiabatic fashion.

2 THEORY

A spin system which is subject to magic-angle sample spinning (MAS) and to a slow variation of a parameter due to an adiabatic process can be described by a time-dependent Hamiltonian $\mathcal{H}(t, T)$. In this notation, the time-variable t characterizes the fast time dependence due to the MAS and the time-variable T describes the slow time dependence due to the adiabatic variation of a spin-system variable. If we assume that the changes due to T can be neglected over a time period $\tau_r = 2\pi/\omega_r$ then we can define a t -time averaged Hamiltonian

$$\mathcal{H}(T) = \langle \mathcal{H}(t) \rangle_{\tau_r} \quad (10)$$

which no longer depends on the time-variable t and is, therefore, independent of the MAS rotation. There are several ways of carrying out the averaging. The most common descriptions use average Hamiltonian and Floquet theory. The details of this averaging process depend on the specific polarization transfer process under discussion. Different approaches have been used and can be found in the original literature (see below).

For a pair of spins $1/2$, the relevant process of the adiabatic polarization transfer can always be described in a subspace κ of the Hamiltonian which is defined by a fictitious spin- $1/2$ system.^{12,13} The T -time dependent system Hamiltonian in this subspace is given by

$$\mathcal{H}^\kappa(T) = \chi^\kappa(T) \cdot S_z^\kappa + |d_{\text{eff}}^\kappa| \cdot (\cos(\varphi)S_x^\kappa + \sin(\varphi)S_y^\kappa) \quad (11)$$

Equation (11) is a trivial generalization of equation (7) caused by the fact that the effective dipolar coupling d_{eff}^κ appearing in the context of recoupling experiments is a complex number with absolute value $|d_{\text{eff}}^\kappa|$ and the phase $\arg(d_{\text{eff}}^\kappa) = \varphi$. The size of $|d_{\text{eff}}^\kappa|$ depends on the two Euler angles α and β which describe the rotation from the principal-axis system of the dipolar interaction tensor to the rotor-fixed coordinate system. The third Euler angle γ determines the phase φ but does not influence the magnitude of the coupling, $|d_{\text{eff}}^\kappa|$. The phase is simply an integer multiple of γ where the integer depends on the matching condition employed. In a powder sample each crystallite has a different Euler angle γ and, therefore, a different phase φ . The Hamiltonian for each crystallite lies in a different plane spanned by the operators S_z^κ and $\cos(\varphi)S_x^\kappa + \sin(\varphi)S_y^\kappa$. To simplify the theoretical description we can rotate the Hamiltonian by the crystallite-dependent angle φ about $-S_z^\kappa$ and recover the simple form of equation (7):

$$\mathcal{H}^\kappa(T) = \chi^\kappa(T) \cdot S_z^\kappa + |d_{\text{eff}}^\kappa| \cdot S_x^\kappa \quad (12)$$

In the course of the adiabatic polarization transfer the effective chemical-shift term is changed from $\chi(0) = \chi_i$ to $\chi(\tau) = \chi_f$ (where χ_i and χ_f have a different sign) in such a way that the adiabaticity condition

$$a(T) = \frac{\sqrt{\chi^\kappa(T)^2 + |d_{\text{eff}}^\kappa|^2}}{|d\Theta^\kappa(T)/dT|} \gg 1 \quad (13)$$

is fulfilled for all times T . Note that the adiabaticity parameter is T -time dependent. Here, the angle $\Theta^\kappa(T) = \arctan(|d_{\text{eff}}^\kappa|/\chi^\kappa(T))$ describes the time-dependent angle between the Hamiltonian and the z -axis. We start at time $T = 0$ with an initial density operator $\sigma^\kappa(0^-) = p^\kappa \cdot S_z^\kappa \approx c \cdot \mathcal{H}^\kappa(0)$ along the z -axis of the subspace κ . If the Hamiltonian $\mathcal{H}^\kappa(0)$ is not parallel with the z -axis, e.g., if the initial offset is not large enough, only the part of the initial density operator that is parallel to the Hamiltonian $\mathcal{H}^\kappa(0)$ has to be taken into account for the further course of the experiment. We denote the density operator just before a projection step at time t by $\sigma^\kappa(t^-)$ and just after the projection step by $\sigma^\kappa(t^+)$. Each projection decreases the spin order because the orthogonal components are assumed to decay irreversibly. After the projection we obtain

$$\sigma^\kappa(0^+) = p^\kappa \cdot \cos(\Theta(0)) S_{\text{eff}}^\kappa(0) \quad (14)$$

where the cosine of the angle $\Theta(0) = \arctan(|d_{\text{eff}}^\kappa|/\chi_i^\kappa)$ determines the initial loss of polarization due to the projection on the operator $S_{\text{eff}}^\kappa(0)$. This projection is schematically illustrated in Figure 2. The operator

$$S_{\text{eff}}^\kappa(T) = \cos(\Theta(T)) S_z^\kappa + \sin(\Theta(T)) S_x^\kappa \quad (15)$$

stays always parallel to the Hamiltonian. Ideally, the sweep is applied such that $\Theta(0) \approx 0$ and

$$\sigma^\kappa(0^+) \approx p^\kappa \cdot S_z^\kappa \quad (16)$$

If the effective coupling $|d_{\text{eff}}^\kappa|$ is non-zero and equation (13) is fulfilled, the density operator always stays parallel to the Hamiltonian (i.e., along $S_{\text{eff}}^\kappa(T)$) and follows the movement of the Hamiltonian and describes an arc in the plane spanned by S_z^κ and $\cos(\varphi) S_z^\kappa + \sin(\varphi) S_y^\kappa$. For $\varphi = 0$, one obtains the following expression for the density operator during the adiabatic sweep:

$$\sigma^\kappa(T) = p^\kappa \cdot \cos(\Theta_i) S_{\text{eff}}^\kappa(T) \quad (17)$$

Figure 2 shows the trajectory followed by the density operator for a single arbitrary crystallite in the plane spanned by S_z^κ and $\cos(\varphi) S_z^\kappa + \sin(\varphi) S_y^\kappa$ as a function of the time-variable T . For a powder each crystallite follows such a trajectory but due

Figure 2 Schematic representation of the adiabatic polarization transfer for a single crystallite orientation in the subspace spanned by S_z^κ and S_x^κ . The initial projection with $\Theta(0)$ the subsequent rotation imposed by the rotation of the Hamiltonian, and the final projection with $\Theta(\tau)$ of the density operator is shown

to the variation in the phase φ for the different crystallites the planes are different. At time $T = 0$ the magnetization of all crystallites are aligned along S_z^κ . At the center of the sweep at $\chi^\kappa(T = \tau/2) = 0$ the magnetization is distributed over the plane spanned by S_x^κ and S_y^κ depending on the value of φ . At the end of the sweep at $T = \tau$ the magnetization of all different crystallites is again aligned but now along $-S_z^\kappa$.

The density operator at the end of the sweep at $\chi^\kappa(\tau) = \chi_f^\kappa$ is then given by

$$\sigma^\kappa(\tau^-) = p^\kappa \cdot \cos(\Theta(0)) \cdot [\cos(\Theta(\tau)) S_z^\kappa + \sin(\Theta(\tau)) S_x^\kappa] \quad (18)$$

where the angle $\Theta(\tau) = \pi + \arctan(|d_{\text{eff}}^\kappa|/\chi_f^\kappa)$. We have to project the density operator at the end of the sweep onto the z -axis of the subspace κ and obtain the final density operator

$$\sigma^\kappa(\tau^+) = p^\kappa \cdot \cos(\Theta(0)) \cos(\Theta(\tau)) S_z^\kappa \quad (19)$$

For a well-designed experiment, we require that $\Theta(0) \approx 0$ and $\Theta(\tau) \approx \pi$ leading to

$$\sigma^\kappa(\tau^+) \approx -p^\kappa \cdot S_z^\kappa \quad (20)$$

The loss of polarization caused by the two projections at the beginning and the end of the sweep are expressed by the factors $\cos(\Theta(0))$ and $\cos(\Theta(\tau))$ in equation (19), respectively, and can be minimized by starting and ending the adiabatic sweep with initial and final values of the effective chemical shift largely exceeding the value of the effective coupling frequency $|d_{\text{eff}}^\kappa|$.

If the effective coupling $|d_{\text{eff}}^\kappa|$ is zero, the density operator is unchanged by the sweep and we obtain a final density operator $\sigma^\kappa(\tau) \approx \sigma^\kappa(0) = p^\kappa \cdot S_z^\kappa$, assuming that $\Theta(0) \approx 0$ and $\Theta(\tau) \approx \pi$.

In principle, any continuous shape for $\chi^\kappa(T)$ can be used which fulfills equation (13), but to minimize relaxation effects it is advantageous to use a sweep which is as short as possible while still maintaining adiabaticity at all times T . The best shape with respect to adiabaticity is a shape where the angular velocity $\alpha(T) = d\Theta(T)/dT$ is proportional to the effective field $\omega_{\text{eff}}(T) = \sqrt{|d_{\text{eff}}^\kappa|^2 + \chi^\kappa(T)^2}$. This requirement is fulfilled for a sweep rate of^{35,36}

$$\frac{d}{dT} \chi^\kappa(T) \propto \frac{(|d_{\text{eff}}^\kappa|^2 + \chi^\kappa(T)^2)^{3/2}}{|d_{\text{eff}}^\kappa|} \quad (21)$$

Such a function leads to a fast change of $\chi^\kappa(T)$ far from the center of the sweep and a slow change close to the center. To design such a sweep, the sweep has to fulfill the condition $\chi^\kappa(\tau/2) = 0$ which is not possible for all spins in the presence of chemical-shift offsets or rf-field inhomogeneity. A linear sweep of

$$\chi^\kappa(T) = \chi_i^\kappa - \left(\frac{\chi_i^\kappa - \chi_f^\kappa}{\tau} \cdot T \right) \quad (22)$$

is the shape which shows the smallest sensitivity to the value of the system parameters but requires the longest sweep time to remain adiabatic during the entire sweep. In practice, a good compromise is to maintain constant angular velocity during the

sweep for a ‘typical’ value of the dipolar coupling constant d_{est} which can be implemented by the function

$$\alpha(T) = \frac{d\Theta(T)}{dT} = \frac{2}{\tau} \cdot \arctan\left(\frac{\chi_i}{|d_{\text{est}}|}\right) \quad (23)$$

Such a solution leads to the functional form

$$\chi^\kappa(T) = |d_{\text{est}}| \cdot \tan\left(\alpha \cdot \left[\frac{\tau}{2} - T\right]\right) \quad (24)$$

for $0 \leq T \leq \tau$ which is more tolerant than the one described by equation (21) to an imprecise estimation of the parameters for the center of the sweep and to the variation of $d_{\text{eff}}(\alpha, \beta, \gamma)$ as a function of the crystallite orientation.

In principle, one can achieve 100% polarization transfer using adiabatic methods compared to a maximum of 73% efficiency using ‘sudden’ methods. This requires of course, that the polarization transfer process is in the adiabatic limit ($a(T) \gg 1$) for all orientation-dependent effective coupling frequencies $d_{\text{eff}}(\alpha, \beta, \gamma)$. This increased efficiency is due to the fact that the transfer speed of the adiabatic polarization transfer is independent of the Euler angles and of the orientation-dependent size of the effective coupling constant. As was shown earlier, the Euler angle γ only influences the phase in the $S_x^\kappa - S_y^\kappa$ -plane where the trajectory crosses but all trajectories reach the final point at the same point in time (Figure 2b).

3 METHODS OF HETERONUCLEAR POLARIZATION TRANSFER

3.1 Hartmann–Hahn Cross Polarization by Adiabatic Passage

Adiabatic Passage Hartmann–Hahn cross polarization (APHH)^{16–21} was designed to combine the advantages of Hartmann–Hahn cross polarization, namely the conservation of the sum polarization, with the advantages of ADRF-ARFF which has a higher transfer efficiency and no critical matching condition. In this experiment the amplitude of one or both of the rf-fields is changed in an adiabatic fashion during the cross-polarization time period (Figure 3) in order to obtain a sweep through the sideband f of the Hartmann–Hahn matching condition $\omega_{1I} - \omega_{1S} = f \cdot \omega_r$.

In the APHH experiment, the sum polarization and σ^Σ are constants of the motion and the relevant subspace of the heteronuclear two-spin Hamiltonian is the zero-quantum subspace $\kappa = \Delta$. The Hamiltonian in this subspace has exactly the form of equation (7)

$$\mathcal{H}^\Delta(T) = \chi^\Delta(T) \cdot S_z^\Delta + |d_{f,\text{eff}}| \cdot S_x^\Delta \quad (25)$$

with $\chi^\Delta(T) = \omega_{1I}(T) - \omega_{1S}(T) - f\omega_r$ where $\omega_{1I}(T)$ and $\omega_{1S}(T)$ are the time-dependent amplitudes of the applied rf fields. The parameter $f = \pm 1, \pm 2$ denotes the sideband of the Hartmann–Hahn matching condition under MAS^{37–39} and $d_{f,\text{eff}}$ is the Fourier coefficient of order f of the heteronuclear dipolar coupling. In APHH CP the initial and final value of the amplitude sweep $\chi_i^\Delta = \omega_{1I}(0) - \omega_{1S}(0) - f\omega_r$ and $\chi_f^\Delta = \omega_{1I}(\tau) - \omega_{1S}(\tau) - f\omega_r$ are limited to about $\pm 1/2\omega_r$.

Figure 3 Pulse sequence used for adiabatic cross polarization. The amplitude modulation during the cross-polarization time can be applied either to the proton (a) or to the carbon (b) channel. Cross polarization uses of phase X

in order not to touch one of the other sideband matching conditions. The fictitious spin-1/2 operators in the zero-quantum subspace are defined as $S_z^\Delta = 1/2 \cdot (I_z - S_z)$, $S_x^\Delta = 1/2 \cdot (S^+ I^- + S^- I^+)$, and $S_y^\Delta = i/2 \cdot (S^+ I^- - S^- I^+)$, where the z -axis (defining I_z and S_z) is chosen along the effective field direction in the rotating frame.⁴⁰ Rotating the density operator in the zero-quantum subspace from S_z^Δ to $-S_z^\Delta$ leads to a complete transfer of magnetization from I_z to S_z because the double-quantum subspace density operator does not evolve during the APHH period of the experiment.

The above description assumes the ideal case of an isolated dipolar-coupled two-spin system where both spins are on-resonance. In the presence of chemical-shift offsets the amplitudes of the rf-fields have to be replaced by the effective fields $\omega_{I,\text{eff}} = \sqrt{(\omega_{1I}(T))^2 + \Omega_I^2}$ and $\omega_{S,\text{eff}} = \sqrt{(\omega_{1S}(T))^2 + \Omega_S^2}$, respectively.⁴⁰ In addition, the effective dipolar-coupling frequency $d_{f,\text{eff}}$ becomes weakly time dependent with T .

Adiabatic cross polarization can also be done using the J coupling as a transfer mechanism in liquid^{41,42} and solid⁴³ samples. If we consider the isotropic J -coupling in addition to the dipolar coupling, we can get polarization transfer under MAS for the $f = 0$ matching condition⁴³ with $d_{0,\text{eff}} = J$. If the system is not isolated but has homonuclear dipolar couplings we can also get polarization transfer for the $f = 0$ and for the $|f| > 2$ matching conditions and the coupling strength of the $f = \pm 1, \pm 2$ matching conditions is modified.

The experimental results of Figure 4 show that adiabatic-passage Hartmann–Hahn cross polarization yields an S-spin signal that is always equal to or larger than the one obtained using Hartmann–Hahn cross polarization with the same contact time. At longer contact times where the transient oscillations⁴⁴ are dying out (in the example of Figure 4 for $\tau > 0.4$ ms) a gain of a factor of two in signal is

Figure 4 Comparison of the cross-polarized magnetization in Hartmann–Hahn cross polarization (solid line) and adiabatic passage Hartmann–Hahn cross polarization (open circles) measured on a sample of 10% $2\text{-}^{13}\text{C}\text{-}3,3,3\text{-}^2\text{H}$ -alanine diluted in perdeuterated alanine. The Hartmann–Hahn cross polarization shows the transient oscillations of the one-bond heteronuclear carbon–proton dipolar coupling as a function of the cross-polarization time τ . The adiabatic passage cross polarization is also shown as a function of the total sweep length and leads to a signal which is larger by a factor of almost two. The experiments were carried out at a spinning speed of $\omega_r/2\pi = 22$ kHz using the $f - 1$ matching condition and a proton field strength of $\omega_{1H}/2\pi = 108$ kHz. (Figure courtesy of René Verel)

observed caused by an improved polarization transfer. The theoretical gain of the APHH CP compared to the conventional cross polarization experiment in larger spin systems (IS_n) have been investigated.²¹ It was found that APHH CP should always outperforms CP by a factor close to two. For a large system with $n \rightarrow \infty$, the theoretical gain is again two²¹ although experimentally much lower gains have been found.¹⁷

A further benefit of the APHH CP experiment is the insensitivity to the matching condition. For small dipolar couplings and fast spinning, the Hartmann–Hahn match is very narrow. It can become quite difficult to match the rf amplitudes and to keep the rf amplitude stable enough over the course of signal accumulation.⁴⁵ An example for such a difficult system is $^{13}\text{C}\text{--}^{15}\text{N}$ cross polarization. For the APHH experiments,²⁰ these difficulties are greatly reduced because the precise matching condition will be fulfilled at some time during the sweep. The exact position does not play a significant role. Figure 5 shows an example of a heteronuclear $^{13}\text{C}\text{--}^{15}\text{N}$ correlation experiment where APHH cross polarization between ^{13}C and ^{15}N was used to establish the chemical-shift correlation.²⁰

An additional gain in signal intensity can be realized due to the relative insensitivity of APHH cross polarization to rf-field inhomogeneities. Only part of the sample is exactly at the Hartmann–Hahn match of the rf-fields in normal cross polarization. This problem is overcome by APHH cross polarization where all spins go through the matching condition but at different times during the sweep. A similar approach can also be used in ‘sudden’ experiments by ramping the amplitude

Figure 5 Chemical shift correlation spectrum for a fully ^{13}C , ^{15}N -labelled sample of the cyclic decapeptide antamanide using adiabatic passage Hartmann–Hahn cross polarization. The resulting spectrum correlates each amide nitrogen N_κ with the directly attached carbons: C_α^κ in the same residue and $\text{C}_{\alpha-1}^\kappa$ in the previous residue. (Figure courtesy of Dr. Andreas Detken)

Figure 6 Multiple adiabatic sweeps through the Hartmann–Hahn matching condition allow the reversible transfer of magnetization between protons and carbons. The experiments were carried out using a sample of 10% $2\text{-}^{13}\text{C}\text{-}3,3,3\text{-}^2\text{H}$ -alanine diluted in perdeuterated alanine. The spinning speed was $\omega_r/(2\pi) = 22$ kHz. The $f = -1$ matching condition and a proton field strength of $\omega_{1H}/(2\pi) = 108$ kHz were used. Each of the four adiabatic sweeps had a length of 2 ms. For comparison we also show the intensity of the magnetization which was obtained in the corresponding Hartmann–Hahn cross-polarization experiment as a function of the cross-polarization time. (Figure courtesy of René Verel)

in a CP experiment.^{46,47} The ramp CP experiment leads to an equilibrium polarization of ca. 50% in two-spin systems even in the presence of rf-field inhomogeneity but the adiabatic gain of an additional factor of two can only be obtained if the design principles for an adiabatic transfer are employed.

The adiabatic gain can be experimentally verified by an experiment where several adiabatic sweeps are performed sequentially as shown in Figure 6. The behavior during the first sweep is completely equivalent to the one in Figure 5. During the second sweep ($2\text{ ms} \leq \tau \leq 4\text{ ms}$) the polarization is transferred back from the ^{13}C spins to the source spin(s), in this case the protons. The whole cycle can be repeated again without noticeable loss of polarization. The polarization in the adiabatic experiments flows back and forth approximately symmetrically around the equilibrium value obtained in a normal CP experiment. The initial jump in the magnetization at $\tau < 1\text{ ms}$ is due to the initial projection of equation (15).

4 METHODS OF HOMONUCLEAR POLARIZATION TRANSFER

4.1 Adiabatic Passage Rotational Resonance

In the adiabatic passage, rotational-resonance experiment (APRR)²³ the frequency of the rotor is changed during the course of the experiment such that the rotor frequency is swept through the rotational-resonance (RR) condition^{24–26} $\Omega_1 - \Omega_2 = n \cdot \omega_r$ in an adiabatic fashion (Figure 7). Such a spinning-frequency sweep can be achieved by suddenly increasing (decreasing) the air pressure on the drive air of the MAS rotor. This can be implemented either by changing

Figure 7 Pulse scheme of the APRR experiment. The pulse scheme follows the basic principle of two-dimensional exchange spectroscopy. The variation of the spinning rate was obtained by using a home-built setup consisting of a parallel arrangement of an air line with a needle valve to control the flow and an air line with a TTL-operated air-valve. This arrangement was placed in parallel with the spinning-speed controller. Upward and downwards spinning-speed ramps were produced by opening or closing the air valve using a user-defined TTL gate from the pulse programmer. Using a 4 mm rotor, a maximum slope of 6000 s^{-2} was obtained. For higher spinning speeds ($>5000\text{ Hz}$) downward ramps perform better, for low spinning speed upward ramps should be used. If a stable spinning frequency during the t_1 and t_2 periods is not required the linear ramp can be extended (dashed line) to include these time periods. (Figure adapted from Ref.²³)

Figure 8 (a) Two-dimensional ^{13}C chemical-shift correlation spectrum of uniformly ^{13}C labelled calcium-acetate monohydrate using RR as a mixing sequence. The strip from the 2D spectrum shows the carboxylic diagonal peaks and the cross peaks to the methyl group region for an experiment recorded at a constant spinning frequency matching the rotational resonance for the spin pair involving the most shielded carboxylic resonance. (b) Two-dimensional ^{13}C chemical-shift correlation spectrum of uniformly ^{13}C labelled calcium-acetate monohydrate using APRR as the mixing sequence. During the mixing time of 40 ms, the spinning frequency was ramped from 1.70 kHz to 1.88 kHz. The APHH passage covered all the $n = 4$ resonances between methyl and carboxylic spins. Four transients were co-added for each of the 256 t_1 increments recorded. The assignment of the resonance lines is given on top of the figure, the chemical shifts are referenced to TMS. Spinning sidebands are denoted by *. (Figure adapted from Ref.²³)

the setting of the spinning-speed controller from the pulse programmer or by using a magnetic valve which opens a bypass high-pressure line.

As the APHH CP experiment, the APRR experiment is a zero-quantum polarization-transfer experiment and the relevant Hamiltonian is the same as for APHH

$$\mathcal{H}^\Delta(T) = \chi^\Delta(T) \cdot S_z^\Delta + |d_{n,\text{eff}}| \cdot S_x^\Delta \quad (26)$$

except that $\chi^\Delta(T) = \Omega_1 - \Omega_2 - n\omega_r(T)$ where Ω_1 and Ω_2 are the isotropic chemical shifts of the two spins. The effective coupling $d_{n,\text{eff}}$ is given by the Fourier component $n = \pm 1, \pm 2$ of the homonuclear dipolar coupling. Again, a rotation of the density operator from S_z^Δ to $-S_z^\Delta$ induced by a variation of the MAS frequency, leads to a full transfer of magnetization from spin 1 to spin 2 as the double-quantum subspace is untouched.

In the presence of a non-vanishing chemical-shielding difference tensor the effective coupling frequencies are somewhat modified and higher-order matching conditions with $|n| > 2$ become allowed.

Figure 9 Pulse sequence for (a) the two-dimensional DREAM correlation experiment and (b) the DREAM spin-pair selective experiments. (c) Four different amplitude shapes which can be used in the spin-pair filter experiment and appropriate modification of the receiver phase. (Figure adapted from Ref.³³)

Figure 10 Cross polarization (a) and DREAM SPS (b) spectra of a mixture of $1\text{-}^{13}\text{C}_1$ -alanine, natural abundance methionine and natural abundance *iso*-leucine. The three substances were mixed in approximately equal weight parts and the sample restricted to the central region of the rotor with a total length of about 3 mm. A total of 3072 scans was co-added for each of the spectra. The spinning frequency was set to $\omega_r/2\pi = 28$ kHz and stabilized within 25 Hz with a spinning speed controller. (Figure adapted from Ref.³²)

One can perform the rotational-resonance experiment also in a tilted frame of reference where the chemical shifts of spins 1 and 2 have to be replaced by the effective fields $\omega_{1,\text{eff}} = \sqrt{(\omega_1(T))^2 + \Omega_1^2}$ and $\omega_{2,\text{eff}} = \sqrt{(\omega_2(T))^2 + \Omega_2^2}$, respectively.^{28–30} Instead of a sweep of the spinning frequency ω_r , one can change the effective fields as a function of T . The experiment is almost completely equivalent to the spinning-frequency ramp except that the variation of $\chi^\Delta(T)$ is now caused by rf-field amplitude changes in full analogy to the APHH experiment.

Figure 8 shows a comparison of a standard RR experiment (Figure 8a) and an APRR experiment (Figure 8b) on a sample of uniformly labelled calcium acetate. The three different resonance lines in the carboxyl region of the spectrum are due to packing effects. The four crystallographically non-equivalent carbonyl carbons give rise to three resolved resonances. The APRR experiment is more broadband and covers all three resolved $^{13}\text{CH}_3\text{--}^{13}\text{COO}$ spin pairs while the RR experiment (Figure 8a) leads to transfer for one of these pairs only. Furthermore, APRR shows much higher cross peak intensity. For a fully adiabatic transfer we would expect all intensity to

be in the cross peaks with no intensity left in the diagonal peaks.

Rotational-resonance experiments on the central transition of a pair of dipolar-coupled half-integer quadrupolar spins can be described in full analogy to the rotational resonance experiments in spin-1/2 nuclei if at least one of the two quadrupolar nuclei has a large quadrupolar coupling constant. In half-integer quadrupolar nuclei the central transition is broadened by the second-order quadrupolar shift. Therefore, the conventional rotational-resonance experiment will only allow polarization transfer for a small number of spins which have an averaged chemical-shift difference close to the selected MAS rotation frequency. If we use a sweep through the rotational-resonance condition of all crystallites, then we are able to achieve recoupling for the whole second-order broadened powder pattern and we obtain polarization transfer independent of the crystallite orientation.²⁷

4.2 DREAM

In the DREAM experiment^{32,33} (Figure 9) a sweep of the rf-field amplitude through the HORROR recoupling condition³¹ $2 \cdot \omega_1 = \omega_r$ is used to transfer polarization between homonuclear dipolar-coupled spin pairs. The relevant subspace of the homonuclear dipolar-coupling Hamiltonian is the double-quantum subspace $\kappa = \Sigma$. The Hamiltonian in this subspace is again of the ‘standard form’ and is given by

$$\mathcal{H}^\Sigma(T) = \chi^\Sigma(T) S_z^\Sigma + |d_{1,\text{eff}}| S_x^\Sigma \quad (27)$$

with $\chi^\Sigma(T) = 2 \cdot \omega_1(T) - \omega_r$ where $\omega_1(T)$ is the time-dependent rf-field amplitude and $d_{1,\text{eff}}$ is the $f = 1$ Fourier component of the homonuclear dipolar-coupling constant. The fictitious spin-1/2 operators are defined as $S_z^\Sigma = (1/2) \cdot (S_{1z} + S_{2z})$, $S_x^\Sigma = (1/2) \cdot (S_1^+ S_2^+ + S_1^- S_2^-)$, and $S_y^\Sigma = (i/2) \cdot (S_1^+ S_2^+ - S_1^- S_2^-)$ where the z -axis (defining S_{1z} and S_{2z}) is along the applied rf-field. A rotation of the density operator from S_z^Σ to $-S_z^\Sigma$ leads to a full transfer of polarization from spin 1 to spin 2 assuming that no zero-quantum transitions take place.

The DREAM recoupling sequence has been used as the mixing scheme in two-dimensional correlation experiments (Figure 9a) and in the context of an efficient homonuclear spin-pair filter (Figure 9b) by combining different shapes for the adiabatic sweep. Such a filter is more efficient than a ‘sudden’ double-quantum filter since not all crystallites need to go through the double-quantum state $S_x^\Sigma \cos(\varphi) + S_y^\Sigma \sin(\varphi)$ at the same point in time. The different amplitude shapes and their corresponding receiver phase are shown in Figure 9c.

Figure 10 shows an application of the DREAM spin-pair filter to the suppression of natural abundance background signals in a mixture of the amino acids alanine, methionine, and *iso*-leucine. The C_α position of alanine was ^{13}C labelled, all other carbon atoms had natural isotopic abundance. The filtered spectrum (Figure 10b) shows only the alanine C_α, C_β spin-pair resonances, all other resonance are attenuated below the noise level. The efficiency of the selection of the adiabatic spin-pair filter is measured to be 61% from the intensity of the CH_3 resonance. The higher intensity of the (100% labeled) C_α resonance compared to the C_β

Figure 11 Two-dimensional ^{13}C chemical shift correlation spectrum of the cyclic decapeptide Antamanide using adiabatic DREAM mixing. The spectrum was recorded at a spinning frequency of $\omega_r(2\pi) = 40$ kHz at a proton Larmor frequency of 500 MHz. (Figure courtesy of Aswin Verhoeven)

resonance can be explained by intermolecular $C_\alpha-C_\alpha$ couplings that allow additional spin pairs to pass partially through the filter and is not due to incomplete suppression of isolated spins.

Figure 11 shows the application of the DREAM sequence as the correlation mechanism in a two-dimensional chemical-shift correlation spectrum. Due to the fact that it is a double-quantum mixing scheme the cross peaks show alternating negative and positive intensities. The spectrum was taken at a MAS frequency of $\omega_r/(2\pi) = 40$ kHz using an rf-field strength at the center of the sweep of $\omega_1/(2\pi) = 20$ kHz. Many dipolar recoupling sequences suffer from the fact that they are more difficult to apply at higher spinning frequencies since the rf-field has to be an integer multiple of the spinning frequency. For DREAM the required rf-field strength is only 1/2 of the spinning frequency which makes the DREAM method very well suited for application at high MAS frequencies. In fact, the method becomes more useful at higher MAS frequencies because the broadbandness of the DREAM mixing with respect to chemical-shift offsets increases linearly with ω_r . As a rule of thumb, the bandwidth of the sequence is approximately equal to $\pm\omega_r/4$. To cover an entire ^{13}C spectrum on a spectrometer with 400 MHz proton resonance frequency, a spinning frequency of about 35 kHz is required.

1 INTRODUCTION

Solid-state NMR provides some of the most powerful techniques for elucidating details of segmental dynamics in solid materials.¹ Such dynamics have important effects on mechanical and conduction properties of polymers, activity of proteins, stability of pharmaceuticals, transport properties in zeolites, and behavior of amorphous materials near the glass transition.^{2–7} While fast dynamics can be characterized to some extent by NMR lineshape analysis and relaxation-time measurements can characterize correlation times over a wide range (see also **Ultraslow Motions in Solids**, Volume 8), the most specific information is obtained in exchange NMR experiments, where relatively slow segmental reorientations with rates of $0.1\text{--}10\,000\text{ s}^{-1}$ are observed in terms of changes of orientation-dependent NMR frequencies.^{1,8–11} Correlation times and their distributions, reorientation-angle distributions, orientational memory, rate memory, the existence of dynamic heterogeneities, and their size can be characterized by 1D, 2D, 3D, and reduced 4D exchange NMR (see **Polymer Dynamics & Order from Multidimensional Solid State NMR**, Volume 6).^{1,12–20} However, the sensitivity and resolution of these traditional exchange-NMR techniques have been limited, since anisotropy-broadened lineshapes or strong sidebands in

magic-angle spinning spectra were required. Only by specific isotopic labeling could these limitations be eliminated in part.

The centerband-only detection of exchange (CODEX) NMR technique has overcome these problems, making it possible to observe and characterize slow ($k = 0.1\text{ s}^{-1}$ to 3000 s^{-1}) segmental reorientations with the highest available NMR sensitivity and site resolution, in sideband-free magic-angle spinning spectra.^{21,22} From short series of one-dimensional macroscopic rotation of the sample (MAS) spectra, the correlation function and correlation time can be determined, and it can be established whether the motion is diffusive or whether it involves jumps between discrete sites, whose number can be measured precisely if all segments are mobile. In addition, motional amplitudes can be estimated, with relatively high sensitivity to small-angle motions. This information is obtained for each site with a resolved line in the sideband-free MAS spectrum.

2 EXCHANGE NMR UNDER MAS, AND ROTOR SYNCHRONIZATION

Figure 1(a) shows the principle of stimulated-echo and exchange-NMR experiments, of which CODEX is an example.^{13,16,23–26} After evolution of transverse magnetization during a time t_1 , one component of the magnetization is stored along the z-direction during the long mixing time t_m . After a 90° read-out pulse, a stimulated echo forms at $t_2 = t_1$ for segments that did not change frequency during t_m . A pure stimulated echo is obtained by storing the two orthogonal components of the magnetization before t_m in alternate transients and combining their signals after read-out pulses of suitable phase (see Figure 1(a)). In a 2D exchange experiment, the time signal during the period t_2 is observed, and the t_1 period is incremented systematically.

The first exchange NMR experiments to measure reorientations under MAS were performed by Kentgens et al.²⁷ Their crucial innovation was the introduction of ‘rotor synchronization’ of the pulse sequence, i.e., making sure that t_m is an integer number of rotation periods, so that the precession of the magnetization resumes at the same rotor orientation where it stopped at the beginning of the mixing time. Otherwise, reorientations of segments relative to the external field occur due to the MAS and overwhelm the more subtle effects of intrinsic segmental reorientations. In later experiments, synchronization with the beginning of the evolution period was also used, in order to achieve pure-phase 2D MAS exchange spectra.²⁸ Recently introduced one-dimensional versions of the sideband-exchange experiment use similar rotor synchronization.^{29,30}

Rotor synchronization for short mixing times can be achieved simply by precise timing of the mixing time. However, for long mixing times, this is not sufficient. For instance, a $\pm 1\text{-Hz}$ deviation from the rotation rate results in a $\pm 36^\circ$ -deviation in the rotor phase after 100 ms, and complete uncertainty of the rotor phase after $t_m = 1\text{ s}$. Therefore, trigger-based active rotor synchronization is necessary. The optical signal of the spinning-speed detector, usually made discrete into ‘high’ and ‘low’ states by a Schmitt trigger, is used to start the pulse sequence at a certain rotor orientation, namely at the transition from high to low or low to high. Based on the trigger, one can resume pulsing at the same rotor orientation tens or hundreds of rotations later. In practice, triggering during a pulse such

Figure 1 (a) Basic stimulated-echo and exchange-NMR pulse sequence. The fundamental time signals that produce the stimulated echo are indicated. Pointed brackets indicate powder averaging. Cosine and sine components measured with the indicated pulse phases are added in subsequent transients. (b) Basic CODEX pulse sequence and its synchronization with the sample rotation. 90° pulses are shown filled. The series of 180° pulses (short open boxes) during t_1 and t_2 recouple the anisotropic chemical shift, while removing the isotropic shift. The xy -8 phase sequence is used for the 180° -pulse trains. Note the change in the phase of the read-out pulse for the sine-component ($+y$ in (a), $-y$ here); it is required to achieve the correct chemical-shift recoupling. (c) Pulse sequence for obtaining the reference signal S_0 , produced by interchanging t_m and t_z in the sequence (b)

as cross polarization should be avoided – in case the trigger signal is absent, the pulse would last indefinitely. To ensure the same rotor orientation at the beginning and end of t_m , the (relatively short) time period between the trigger signal and the start of t_m is reproduced after a trigger signal near the end of t_m . This is indicated by the bold arrows at the bottom of Figure 1(b). Consistent triggering requires the trigger mark on the rotor to be sharp; in practice, a straight pen mark is found to be sufficient.

3 EXPLANATION OF THE CODEX PULSE SEQUENCE

Simply put, CODEX is a stimulated-echo experiment under MAS conditions, with chemical-shift-anisotropy recoupling and intensity referencing in the tradition of REDOR.³¹ Figure 1(b) shows the CODEX pulse sequence. After cross-polarization (or single-pulse excitation), the magnetization evolves under the anisotropic chemical shift, recoupled by a series of 180° pulses spaced by $t_r/2$.^{22,32} Then, one component of the magnetization is stored for the mixing time t_m , during which motion can occur. The mixing time is a multiple of the rotation period t_r . In successive transients, the phases of the 90° -pulses that bracket the mixing time are changed together by 90° , so that both components, $\cos \Phi_1$ and $\sin \Phi_1$, of the magnetization are retained alternately. If the storage pulse and the read-out pulse always have opposite signs, the sum of two transients yields $\cos \Phi_1 + i \sin \Phi_1$. Except for a scaling factor of 0.5, the signal is effectively the same as if no 90° -pulses

and mixing time had been applied, and a rotor echo forms at the end of the second recoupling period ($t_2 = t_1$).

The total phase $\Phi_1 + \Phi_2 = |\Phi_2| - |\Phi_1|$ of the magnetization at the end of the second recoupling period of duration $N/2 t_r$ is obtained from

$$\Phi_1 = \frac{N}{2} \left(- \int_0^{t_r/2} \omega_1(t) dt + \int_{t_r/2}^{t_r} \omega_1(t) dt \right) = -N \int_0^{t_r/2} \omega_1(t) dt \quad (1a)$$

$$\Phi_2 = \frac{N}{2} \left(\int_0^{t_r/2} \omega_2(t) dt - \int_{t_r/2}^{t_r} \omega_2(t) dt \right) = N \int_0^{t_r/2} \omega_2(t) dt \quad (1b)$$

with the frequencies $\omega_1(t)$ and $\omega_2(t)$ before and after t_m , respectively.²² In the second step of equation (1a), a standard result of recoupling of inhomogeneous NMR interactions (e.g., chemical shift anisotropy or spin-pair dipolar couplings) was used.^{31,32} If $\omega_1(t) = \omega_2(t)$, i.e., if no exchange occurs, equation (1) leads to $\Phi_1 + \Phi_2 = |\Phi_2| - |\Phi_1| = 0$; in other words, the magnetization is refocused in a stimulated echo along its original direction.

At the end of the second recoupling period, the total magnetization is along the original direction that it had during CP. The full magnetization is stored along the z -axis during the period t_z , and subsequently read out for detection. To suppress spinning sidebands during detection, the total suppression of sidebands (TOSS) sequence can be used before detection.³³ Since motion-induced dephasing can break the cylindrical symmetry around the rotor axis required for TOSS, the duration of t_z is incremented in K steps over a full rotation period.¹ This ensures that TOSS suppresses all sidebands except for orders nK (for details see deAzevedo et al.).²²

In a simple CODEX experiment, the signal intensity $S(t_m, \delta N t_r)$ is observed; here we have normalized the time $N t_r$ with the chemical-shift anisotropy parameter δ .¹ To remove effects of T_1 relaxation during t_m and of T_2 relaxation during $N t_r$, a reference spectrum $S_0 = S(0, \delta N t_r)$ is required that has all the same relaxation factors but no motion during t_m . This is achieved by simply interchanging the durations of t_m and t_z , see Figure 1(c). More generally, the requirement is that in the reference experiment t_m is sufficiently short ($t_m = t_r < 1$ ms) while the sum $t_m + t_z$ is the same as in the actual CODEX spectrum. In practice, effects of spectrometer drift are minimized by alternating measurements between CODEX signal S and reference signal S_0 approximately every five minutes. The ratio $S(t_m, \delta N t_r)/S(0, \delta N t_r)$ can be plotted as a function of t_m or $\delta N t_r$, to characterize the correlation function or the motional geometry, respectively.

Often, it is advantageous to subtract the CODEX spectrum $S = S(t_m, \delta N t_r)$ from the reference spectrum $S_0 = S(0, \delta N t_r)$, to obtain a pure-exchange CODEX spectrum $\Delta S = S_0 - S$. In this difference spectrum, the signals of non-exchanging components are removed from the spectrum. Figure 2(a) shows an example of this procedure for glassy poly(methyl methacrylate), PMMA, measured near ambient temperature. In Figure 2(b), a series of pure-exchange CODEX spectra of PMMA are plotted as a function of the mixing time; they show that some of the sidegroups of this polymer are undergoing large-amplitude motions in the glassy state.^{17,34}

The pure-exchange approach can also serve as a useful ‘filter’ for the signals of slowly-moving groups in a multi-component system.

The normalized pure-exchange CODEX intensity is given by

$$E(t_m, \delta N t_r) = \frac{\Delta S(t_m, \delta N t_r)}{S(0, \delta N t_r)} = \frac{S(0, \delta N t_r) - S(t_m, \delta N t_r)}{S(0, \delta N t_r)} \quad (2)$$

The nomenclature was chosen in analogy to REDOR, where the normalized dephasing provides information on internuclear distances.^{31,22}

The t_m -dependence of the pure-exchange CODEX intensity for PMMA and two crystalline model compounds, dimethyl sulfone (DMS) and methylmalonic acid, is plotted in Figure 3(a). The resulting curves correspond to the correlation functions of these dynamics on the millisecond time scale. For DMS, a single-exponential curve is obtained, while PMMA shows some non-exponentiality. Methylmalonic acid shows no exchange except for ^{13}C spin diffusion (see Section 5.1). In Figure 3(b), exchange due to helical jumps in the crystallites of isotactic polypropylene is shown.^{28,21}

4 ANALYSIS AND SIMULATION OF CODEX CURVES

4.1 Reorientation-Angle Analysis Based on the Difference Tensor

CODEX can give more information than just the correlation function obtained by recording the intensity as a function of t_m . Through variation of the duration $N t_r$ of the evolution under the recoupled CSA, the amplitude of the reorientations during t_m can be determined. The nuclear spins evolve for $N/2$ rotor periods with the phase Φ_1 before t_m , and for $N/2$ rotor periods with the corresponding phase Φ_2 after t_m . The dephasing factor

Figure 2 (a) Full reference spectrum S_0 , spectrum S after CODEX dephasing and pure-exchange CODEX spectrum $\Delta S = S_0 - S$ of unlabeled PMMA at 300 K, for $t_m = 500$ ms and $N t_r = 800$ μs . The intensity of ΔS is low since only a minority of the sidegroups (35%) are undergoing flips. (b) Series of pure-exchange CODEX spectra of PMMA at 300 K, $\nu_r = 6.5$ kHz, and $N t_r = 615$ μs , as a function of t_m as indicated. For the COO carbon, $\delta N t_r = 8\pi$; for the OCH₃ group, $\delta N t_r = 3.8\pi$. Large-amplitude side-group and smaller-amplitude backbone motions are observed

Figure 3 Correlation functions of slow segmental motions obtained from the normalized pure-exchange CODEX intensities $\Delta S/S_0 = E(t_m, \delta N t_r)$ as a function of t_m for (a) COO groups in methylmalonic acid ($T = 300$ K, $\delta N t_r = 7.6\pi$); COO groups in PMMA ($T = 288$ K, $\delta N t_r = 8\pi$); CH_3 groups in DMS ($T = 288$ K, $\delta N t_r = 12.4\pi$); and (b) CH and CH_2 groups in iPP ($T = 365$ K; $\delta N t_r = 3.6\pi$ and 8.5π , respectively). On the right, the expected final intensity values for M-site jumps are marked

modulating the amplitude of the signal component detected in the CODEX MAS signal is therefore

$$\frac{S(t_m, \delta N t_r)}{S(0, \delta N t_r)} = \text{Re}(\exp(i(\Phi_1 + \Phi_2))) = \langle \cos(|\Phi_2| - |\Phi_1|) \rangle$$

$$= \left\langle \cos \left(N \int_0^{t_r/2} (\omega_2(t) - \omega_1(t)) dt \right) \right\rangle \quad (3)$$

The pointed brackets indicate the powder average, which also contains the effect of the correlation time τ_c and mixing time t_m . Note that according to equations (2) and (3), the pure-exchange signal is related directly to the dephasing factor, $E(t_m, \delta N t_r) = 1 - S(t_m, \delta N t_r)/S_0$. In equation (3), the phase $|\Phi_2| - |\Phi_1|$, which depends on $\delta N t_r$ and the reorientation angles ($\alpha_R, \beta_R, \gamma_R$), can be considered as the phase acquired within a time of $N/2 t_r$ under the action of the chemical-shift difference tensor

$$\vec{\sigma}^\Delta = (\vec{\sigma}_2 - \vec{\sigma}_1) \quad (4a)$$

since

$$\omega_2 - \omega_1 = -\gamma B_0 \frac{\vec{B}_0^T}{B_0} (\vec{\sigma}_2 - \vec{\sigma}_1) \frac{\vec{B}_0}{B_0} \quad (4b)$$

The ‘width’ (principal-value range) $\gamma B_0 N |\sigma_{33}^\Delta - \sigma_{11}^\Delta|$ of the scaled chemical-shift difference tensor $\gamma B_0 N \vec{\sigma}^\Delta$ relative to the spinning speed ω_r determines whether there is significant dephasing due to the anisotropy, i.e., whether the experiment is sensitive to the segmental reorientation. By increasing the number of rotor cycles N , we can enhance the anisotropy to large values $\gamma B_0 N |\sigma_{33}^\Delta - \sigma_{11}^\Delta| \gg \omega_r$. The useful role of the difference tensor in CODEX simulations will be discussed in Section 4.3 below.

Uniaxial interactions, i.e., with $\eta = 0$, are particularly convenient to treat analytically, because only the unique principal axis needs to be considered. This case is also quite commonly found, e.g., for dipolar couplings in a spin pair or for the ^2H quadrupolar coupling. Therefore, it is instructive to calculate the difference tensor analytically for $\eta = 0$. Due

to the uniaxiality, the reorientation is fully characterized by a single reorientation angle β_R between the unique principal axis before and after the mixing time. In the specific case of $\eta = 0$, the principal values of the difference tensor are $\sigma_{22}^\Delta = 0$ and the full-width anisotropy $|\sigma_{33}^\Delta - \sigma_{11}^\Delta|$ of the difference tensor, i.e., the range of possible frequency differences, is^{22,35}

$$|\sigma_{33}^\Delta - \sigma_{11}^\Delta| = |(\sigma_{33} - \sigma_{11}) 2 \sin \beta_R| \quad (5)$$

This represents a strong linear dependence on the reorientation angle for $\beta_R < 45^\circ$, which permits relatively easy detection of small-angle motions. It compares favorably with the more common $(3 \cos^2 \beta_R - 1)/2$ angle dependence, which is insensitive to β_R for $\beta_R < 15^\circ$.

Figure 4(a) shows simulated pure-exchange CODEX curves as a function of $\delta N t_r$ for different reorientation angles β_R . The predicted sensitivity to small-angle motions is clearly recognizable. Experimental data points for DMS are also shown. In Figure 4(b), the pure-exchange CODEX intensity $E(\delta N t_r)$ for helical jumps in the crystallites of isotactic polypropylene (iPP) at 365 K and for backbone motion in glassy PMMA at 293 K are shown.^{21,28,36} Based on the unitless variable $\delta N t_r$, the motion of iPP is immediately recognized as being of large amplitude, while the methylene groups in the backbone of PMMA reorient by approximately 10° .²²

For a non-uniaxial interaction, the reorientation of a principal-axes system must be described in terms of three transformation coordinates. As already indicated above, these are usually chosen as the Euler angles $\alpha_R, \beta_R, \gamma_R$ between the initial and final PAS orientations. As in the case of $\eta = 0$, calculations of the width of the difference tensor $|\omega_{33}^\Delta - \omega_{11}^\Delta|$ for general values of η show an initial linear dependence on the reorientation angles β_R and $\varepsilon_R = \alpha_R + \gamma_R$. This can be generally proved by calculating the eigenvalues of the difference tensor for small values of β_R and ε_R .²²

A simple result is also found for the case of a rotation by an angle β'_R around the n 'th principal axis of the interaction tensor $\vec{\sigma}$. Here, $\sigma_{22}^\Delta = 0$ and

$$|\sigma_{33}^\Delta - \sigma_{11}^\Delta| = |(\sigma_{kk} - \sigma_{mm}) 2 \sin \beta'_R| \quad (6)$$

Figure 4 Measurement of the motional amplitude by recording normalized pure-exchange CODEX intensities $\Delta S/S_0 = E(t_m, \delta N t_r)$ as a function of $\delta N t_r$. (a) DMS at 288 K, $t_m = 75$ ms, and $\nu_r = 5.5$ kHz. Also shown are simulations, for $\eta = 0$, of reorientations of the unique principal axis by 10° or 170° , 20° or 160° , 30° or 150° , 50° or 130° , and 70° to 110° (curves in this large-amplitude range are virtually indistinguishable). (b) CODEX intensities $E(t_m, \delta N t_r)$ as a function of $\delta N t_r$ for isotactic polypropylene (iPP) at 365 K, $t_m = 1$ s, and for the backbone of glassy PMMA at 293 K, $t_m = 0.5$ s. Comparison with (a) immediately shows that the motions in iPP are of large amplitude, while those of the PMMA backbone are restricted

where n , k , and m label the three principal axes of $\vec{\sigma}$. This is completely analogous to equation (5).

The quantitative analysis of CODEX data requires knowledge of three principal values of the chemical shift tensor, or at least of the chemical-shift anisotropy parameter δ . These values can be obtained in a variety of ways. A first estimate can be obtained based on the tabulated CSA principal values of similar chemical groups.³⁷ Various methods of experimental CSA measurements have been described in the literature.^{38–40} The estimation of $|\delta|$ by CSA recoupling under MAS very similar to CODEX has been demonstrated by deAzevedo et al.²²

In a view traditionally taken in REDOR, rather than considering N as scaling the difference tensor relative to the spinning speed, it is considered that $N t_r$ is the total time of evolution under the influence of the anisotropic interaction.³² Then it is found that the dephasing is independent of the spinning speed and only depends on the total time $N t_r$.²² Due to this ω_r -independence, the CODEX pulse sequence works up to very high spinning speeds.

4.2 The Role of the Reorientation-Angle Distribution

In the case of a uniaxial NMR interaction, i.e., $\eta = 0$, the information content of an exchange experiment at a given mixing time t_m can be summarized in terms of the reorientation-angle distribution $R(\beta_R, t_m/\tau_c)$, i.e., the probability density of finding a reorientation angle β_R after a mixing time t_m .^{1,14,16,41} Since the correlation time τ_c is the natural reference for t_m , only their ratio, t_m/τ_c , is relevant for the reorientation-angle distribution. The dephasing or pure-exchange intensity CODEX curves are simply $R(\beta_R, t_m/\tau_c)$ -weighted superpositions of the CODEX curves $\varepsilon(\delta N t_r; \beta_R)$ for specific β_R

values.^{16,42}

$$E(t_m, \delta N t_r) = \int_0^{90^\circ} R\left(\beta_R, \frac{t_m}{\tau_c}\right) \varepsilon(\delta N t_r; \beta_R) d\beta_R \quad (7)$$

The integration weighting by $\sin \beta_R$ is contained in $R(\beta_R, t_m/\tau_c)$. The calculation of $\varepsilon(\delta N t_r; \beta_R)$ is outlined in equation (10) below. Note that while all $\varepsilon(\delta N t_r; \beta_R)$ have the same shape except for the $\sin \beta_R$ – scaling of their x-axes, their superposition $E(t_m, \delta N t_r)$ in general has a different shape (to visualize this, consider that similarly the sum of Gaussian bell curves of different widths, even when they have the same center, is not a Gaussian). For a few motional models, the reorientation-angle distributions $R(\beta_R, t_m/\tau_c)$ and corresponding $E(\delta N t_r; t_m)$ curves are shown in Figure 6. They will be discussed in more detail below.

For non-uniaxial interactions, β_R in this discussion and in equation (7) should be replaced with the full set of reorientation angles $(\alpha_R, \beta_R, \gamma_R)$. For specific motions, other angular variables may be more convenient. For rotations around a given axis, such as the helix axis in helical jumps or the invariant axis in uniaxial rotational diffusion, the angle ψ of rotation around that axis is most convenient.

4.3 Simulation Procedure

For simulations of CODEX curves, each subcurve $\varepsilon(\delta N t_r; \alpha_R, \beta_R, \gamma_R)$ needed for equation (7) is calculated based on equation (3), using the following steps:

- (i) Choose a convenient frame to rotate $\vec{\sigma}_1$ to $\vec{\sigma}_2$. In this frame, $\vec{\sigma}_1$ is expressed by a 3×3 matrix, and the rotation can be performed using Cartesian rotation matrices,

$$\vec{\sigma}_2 = \vec{R}(\alpha_R, \beta_R, \gamma_R) \vec{\sigma}_1 \vec{R}^T(\alpha_R, \beta_R, \gamma_R) \quad (8)$$

or, alternatively, Wigner rotation matrices. The rotation is defined by the Euler angles $\alpha_R, \beta_R, \gamma_R$ or by other angles specifying the motion that the segment is supposed to undergo (e.g., the rotation angle around a given axis).

- (ii) Calculate the difference tensor (3×3 matrix) $\vec{\sigma}^\Delta = (\vec{\sigma}_2 - \vec{\sigma}_1)$.
- (iii) Determine the principal values of $\vec{\sigma}^\Delta$ (i.e., diagonalize $\vec{\sigma}^\Delta$). Calculate its anisotropy parameter δ_Δ and asymmetry parameter η_Δ .
- (iv) We can evaluate the integral in equation (3) as follows,

$$\begin{aligned} \int_0^{t_r/2} (\omega_2(t) - \omega_1(t)) dt &= \int_0^{t_r/2} \omega^\Delta(t) dt \\ &= \tilde{S}_1(\delta_\Delta, \eta_\Delta, \alpha_\Delta, \beta_\Delta, \gamma_\Delta) \frac{t_r}{2} \\ &= \delta_\Delta \sqrt{2} \left\{ \frac{1}{3} \eta_\Delta \sin 2\alpha_\Delta \sin \beta_\Delta \cos \gamma_\Delta \right. \\ &\quad \left. + \frac{1}{2} \sin 2\beta_\Delta \left(1 + \frac{1}{3} \eta_\Delta \cos 2\alpha_\Delta \right) \right. \\ &\quad \left. \times \sin \gamma_\Delta \right\} \frac{t_r}{2} \end{aligned} \quad (9)$$

using the Euler angles $\alpha_\Delta, \beta_\Delta, \gamma_\Delta$ that specify the orientation of the principal-axes system of the difference

tensor in the rotor-fixed frame. The subcurve $\varepsilon(\delta N t_r; \alpha_R, \beta_R, \gamma_R)$ can now be expressed as

$$\begin{aligned} \varepsilon(\delta N t_r, \alpha_R, \beta_R, \gamma_R) &= 1 - \left\langle \cos \left(N \int_0^{t_r/2} (\omega_2(t) - \omega_1(t)) dt \right) \right\rangle \\ &= 1 - \left\langle \cos \left[\frac{\tilde{S}(\delta_\Delta, \eta_\Delta, \alpha_\Delta, \beta_\Delta, \gamma_\Delta) N t_r}{2} \right] \right\rangle_{\alpha_\Delta, \beta_\Delta, \gamma_\Delta} \end{aligned} \quad (10)$$

with $\tilde{S}(\delta_\Delta, \eta_\Delta, \alpha_\Delta, \beta_\Delta, \gamma_\Delta)$ as given in equation (9). The pointed brackets represent only the powder average over $\alpha_\Delta, \beta_\Delta, \gamma_\Delta$, i.e., the orientation of the chemical-shift difference tensor. In contrast, in equation (3) the average also included a summation over all reorientation angles. The powder average in equation (10) is calculated numerically.

- (v) Go back to (i) to repeat the calculation for a different set of reorientation angles, yielding a different CODEX subcurve.
- (vi) Obtain the CODEX curve $E(t_m, \delta N t_r)$ by superimposing the $\varepsilon(\delta N t_r; \alpha_R, \beta_R, \gamma_R)$ subcurves weighted with the reorientation angle distribution $R(\alpha_R, \beta_R, \gamma_R, t_m/\tau_c)$ for the t_m under consideration, according to equation (7).

4.4 Number of Accessible Orientations and Fraction of Mobile Segments

In complex systems such as amorphous polymers, broad distributions of correlation times and motional amplitudes often result in a complex exchange behavior. It is often a good approximation to analyze such situations in terms of a fraction f_m of significantly exchanging segments, and a component $(1 - f_m)$ that does not exchange significantly and therefore can be treated as immobile. The case of a homogeneous system in which all equivalent segments are moving similarly, as is true for most crystals, is obtained by setting $f_m = 1$.

Information about the fraction f_m and the number M of equivalent orientational sites accessible to the mobile segments is obtained from the long-time exchange intensity E_∞ . Since a fraction $1/M$ of the mobile species will reside in the originally selected site, see Figure 5, we have

$$E_\infty = E(t_m \gg \tau_c, \delta N t_r \gg 1) = f_m \left(1 - \frac{1}{M} \right) \quad (11)$$

For $f_m = 1$, the minimum E_∞ is $1/2$, obtained for $M = 2$. For diffusive reorientations of all segments, $M \gg 1$ and $E_\infty \sim 1$; note, however, that for restricted diffusion, very large phases

Figure 5 Relation between the final exchange intensity and the number of sites in an M-site jump process. At long times ($t_m \rightarrow \infty$), $1/M$ of the segments reside in the original site. Thus, the final exchange intensity E_∞ deviates from unity by $1/M$

$\delta N t_r$ will be required to reach the final state. Also, if $E_\infty < 1/2$, $f_m < 1$. In fact, equation (11), with $M = 2$ and $M \rightarrow \infty$, yields rigorous limits for f_m in terms of E_∞ :

$$E_\infty < f_m \leq 2E_\infty \quad (12)$$

From E_∞ alone, f_m and M cannot be determined unambiguously. Fortunately, the number of sites M can be measured in a four-time CODEX experiment, which is produced by concatenating two CODEX pulse sequences.²² In the first CODEX difference experiment with mixing time t_{ma} , the mobile groups are selected; then their exchange behavior, with a final value of $1/M$, is characterized selectively in another CODEX MAS section by changing the mixing time t_{mc} . Effects of T_1 relaxation decay can be eliminated by keeping the total z-period $t_{mc} + t_z$ constant. Therefore, no difference is required in the second half of the experiment. The four-time CODEX experiment has close analogies to a reduced four-dimensional (4D) exchange NMR experiment, where the orientation-dependent frequency is probed at four different times.¹⁸ The reduced 4D exchange method, and the closely related four-time exchange experiment have been used to identify the origins of the non-exponential loss of correlation above the glass-transition temperature and to estimate the size of dynamic heterogeneities.^{18–20} Four-time CODEX will make such studies much more sensitive and quantitative.

4.5 Jumps vs. Diffusive Motions

A variety of different motional models have been considered in the literature.^{1,14} They can be grouped into jump processes and diffusive motions. For instance, symmetric N-site exchange is a common jump process, while isotropic rotational diffusion is the most important example of a diffusive reorientation. Defining distinctions between pure jumps and pure diffusion are seen in the evolutions of their reorientation-angle distributions $R(\beta_R, t_m/\tau_c)$ with time t_m ; this behavior can be used in CODEX NMR to identify pure jump motions and diffusive motions. The $R(\beta_R, t_m/\tau_c)$ of four classical motional models and the corresponding CODEX curves $E(\delta N t_r, t_m)$ are shown in Figure 6.

All diffusive motions produce a characteristic change in the shape of $R(\beta_R, t_m/\tau_c)$ with increasing t_m . The sharp peak at $\beta_R = 0^\circ$ gradually broadens and approaches the wide distribution characteristic of the final stage, such as $\sin \beta_R$ for isotropic diffusion. As a result, the shape of the $E(\delta N t_r)$ CODEX curves depends strongly on t_m : For short t_m , the curves rise quite slowly because only small reorientation angles have been reached, while an earlier and faster increase in $E(\delta N t_r)$ (plotted as a function of $\delta N t_r$, with t_m only as a parameter) occurs at long t_m when larger reorientation angles have been attained. These features are clearly visible in Figures 6(c) and 6(d), where isotropic and uniaxial rotational diffusion, respectively, have been simulated.

In contrast, for many pure jump motions the only change in the reorientation-angle distribution is the relative intensity of the reorientation-angle distribution at $\beta_R = 0$ and at $\beta_R \neq 0$. This holds for all two-site jumps, circular three-site jumps, random N-site jumps, and the isotropic random-jump model. As a result, the shape of the $E(\delta N t_r, t_m)$ curves does not change

Figure 6 Time evolution of the reorientation-angle distributions $R(\beta_R, t_m/\tau_c)$ for four important motional models, and the corresponding CODEX $E(\delta N t_r, t_m)$ curves (for a uniaxial interaction, $\eta = 0$). As indicated at the top, the line thickness decreases with increasing t_m/τ_c ($=0.1, 0.3, 1.0, 3.0$, and 10). (a) Three-site jumps, with a 109° (or equivalently 71°) jump angle. (b) Random isotropic jumps. In this model, all orientations are equally likely after the jump. (c) Isotropic rotational diffusion, without amplitude limitation. (d) Uniaxial rotational diffusion on a cone with an apex angle of 141° (or equivalently $2 \cdot 109.5^\circ$). The dashed arrows in the plots indicate the characteristic differences between the t_m/τ_c dependences for jump motions (a,b) and diffusion (c,d)

with t_m . Only its height (y-scale) increases. This is clearly visible in Figures 6(a) and (b).

Helical jumps, where sites along a helical chain are accessed sequentially, do not fall under this category, if the chain forms a 4_n helix (i.e., 4 repeat units in n turns) or more complex helix.^{1,27} Nevertheless, their change in reorientation-angle distribution is still characteristically different from that of diffusive motions. The peak at $\beta_R = 0$ does not broaden, and $R(\beta_R, t_m/\tau_c)$ consists only of a few sharp peaks whose relative height changes only slowly. The rise for short t_m will be fast and unchanged, being due to large-angle jumps between neighboring sites; only at long t_m will changes be observed due to the contribution of non-neighboring sites.

Another characteristic aspect of diffusive motions is that the number of sites M is infinite. Thus, at sufficiently large $\delta N t_r$ and t_m , full exchange will be observed. This property is shared with only a very small number of pure jump processes; the isotropic random-jump model, Figure 6(b), is the only prominent example.

However, it should be noted that $M \rightarrow \infty$ is also a property of limited diffusion superimposed on jumps. Such a combined process may still be relatively difficult to distinguish from pure diffusion, in particular if the diffusion has a broad distribution of correlation times.

5 PRACTICAL CONSIDERATIONS

5.1 Spin Exchange by Dipolar Couplings

Segmental dynamics is not the only possible exchange process. Two effects based on dipolar couplings also lead to exchange of anisotropic interactions and intensity changes in the CODEX experiment. The first is relaxation-induced dipolar exchange due to dipolar couplings to heteronuclei, in particular ^{14}N and ^{15}N , that undergo significant longitudinal relaxation during t_m .^{43,44} The relaxation removes a heteronuclear coherence term from the density operator and thus reduces the stimulated echo. This effect has been described in detail by Saalwächter and Schmidt-Rohr.⁴⁴ Due to the small value of the nitrogen-carbon dipolar coupling, it is a significant problem only for CODEX experiments involving nitrogen-bonded carbon sites with small chemical-shift anisotropies. On the other hand, this relaxation-induced dipolar exchange with recoupling can be exploited to measure internuclear distances between heteronuclei.⁴⁴

The more common second effect is ^{13}C spin diffusion or spin exchange generated by homonuclear dipolar couplings and affected by the ^1H - ^{13}C dipolar coupling.^{45–48} For ^{13}C in natural abundance, it typically generates 4% exchange intensity within 0.5 s. In isotopically labeled materials, it can occur significantly within 50 ms. Apart from isotopic dilution, the only known procedure for slowing down ^{13}C spin exchange between sites with similar isotropic chemical shifts is to increase the spinning speed. Among the experiments for measuring exchange by segmental reorientation, CODEX is the only one that is compatible with high spinning speeds. We have recently shown that for unprotonated sites, an increase of the spinning speed from 8 to 28 kHz indeed decreases the spin exchange rate by a factor of 3–10.⁴⁹ Thus, CODEX under fast MAS can significantly extend the range of correlation times accessible to exchange NMR measurements.

In ^{13}C -enriched proteins, Hong et al. have circumvented the ^{13}C spin diffusion problem by performing a ^{15}N CODEX experiment followed by ^{15}N - ^{13}C transfer and ^{13}C detection.⁵⁰ The dipolar couplings between the ^{15}N nuclei, which are separated by three bonds and have smaller gyromagnetic ratios, are more than an order of magnitude reduced relative to those of ^{13}C in a uniformly labeled protein.

5.2 Accessible Range of Correlation Times

The rates for which dephasing is observed in CODEX NMR range from ~ 0.1 to $\sim 5000 \text{ s}^{-1}$. Very slow motions, which require long mixing times, can be studied better by CODEX than by any other NMR technique. The high sensitivity and good dynamic range of CODEX NMR enables detection of the $\sim 10\%$ exchange intensity that arises already within $t_m = 0.1 \tau_c$, and makes it less sensitive to signal reduction by T_1 -relaxation and the increased experiment duration when the mixing time exceeds the recycle delay. Exchange due to ^{13}C spin exchange (see above) which competes with motional exchange, is the main limitation for detecting very slow motions. Even in this aspect, CODEX is often superior. Not only can CODEX under fast MAS slow down spin diffusion among unprotonated carbons but its superior sensitivity also permits a reduction in the isotopic labeling level, or even measurements on ^{13}C in natural abundance.⁴⁹ This is

particularly relevant for systems that previously required ^{13}C enrichment for achieving sufficient sensitivity, e.g., benzene undergoing jumps and diffusion in zeolites.⁶

To understand the effect of motions on the 100- μs time scale on CODEX, consider that a clean exchange experiment requires that no motion occurs during the dephasing and rephasing periods Nt_r (i.e., $k < 1000\text{ s}^{-1}$). Nevertheless, even with frequency changes during those periods, some motional dephasing will occur. Its strong dependence on the dephasing time and near independence from the mixing time will identify its high rate.

Finally, motions with rates exceeding the chemical-shift anisotropy significantly will not be detected by CODEX, since the motionally averaged frequencies do not change during the course of the experiment. This will lead to a reduction in E_∞ , and care must be taken not to interpret these fast-moving segments as immobile. Fortunately, significant motions with rates exceeding $10\,000\text{ s}^{-1}$ can be detected by other NMR experiments.^{9–11,51,52}

5.3 Implementation of the CODEX Pulse Sequence

Due to the simplicity of the CODEX pulse sequence, the implementation of the technique is mostly straightforward. However, since the method relies on measuring signal amplitudes rather than frequency positions, some care should be taken to avoid artifacts. A fixed xy-8 phase sequence is used for the train of 180° pulses that recouple the CSA.⁵³ Effects of pulse imperfections and T_1 relaxation are minimized or eliminated using the phase cycling given by Reichert et al.⁴⁹

For protonated carbon sites, in particular CH_2 groups, the residual C–H dipolar coupling during the multiple 180° pulses leads to significant dephasing. Fortunately, this does not affect the normalized CODEX data, since the same dephasing occurs in the reference experiment. However, the intensity is degraded. The decoupling is excellent if the ^1H B_1 field strength during the ^{13}C pulses is so high that the duration of a ^{13}C 180° pulse corresponds to a $3 \times 180^\circ$ pulse length on protons.⁵⁴ In order to reduce the ^1H power required to achieve this condition, it can be advantageous to increase the duration of the ^{13}C 180° pulses, i.e., to *reduce* the ^{13}C pulse power.

6 APPLICATIONS OF CODEX

6.1 Dynamics in Complex Glassy Polymers

So far, NMR studies of slow segmental motions of unlabeled polymers in the glassy state have been virtually impossible, due to sensitivity and line-overlap problems. CODEX and its non-spinning analog, 1D PUREX, enable detailed, quantitative studies of these dynamics.²⁵ The selective observation of exchanging sites in pure-exchange CODEX and 1D PUREX spectra leads to a great increase in resolution and in the dynamic range, which in turn reduces artifacts arising from the often dominant signals of immobile sites.

Examples for the detection of flipping sidegroups in PMMA by CODEX are shown in Figures 2 and 3. The characterization of the motion as a jump process between $M = 2$ sites was confirmed in PMMA by 4-time CODEX.²² Extending these experiments to a series of glassy poly(*n*-alkyl methacrylates) with COOR sidegroups of various sizes, CODEX has revealed

that even some large cyclohexyl sidegroups can flip, but that the flipping fraction is only 9%.⁵⁵ Surprisingly, the fraction of flipping sidegroups was found to remain temperature-independent in PMMA with its small methylester sidegroup, while it increases significantly with temperature in polymers with longer sidegroups.⁵⁵ In polyphenylene dendrimers, slow dynamics in the highest-generation phenylene rings has been observed by CODEX.⁵⁶ Generally, CODEX enables us to study almost any slow dynamic process in polymers and thus learn more about the relation between chain motions and mechanical properties.

6.2 Dynamics in Peptides and Proteins

In biological systems, knowledge of the three-dimensional molecular structure is important, but further insight into the segmental dynamics is also highly valuable. Segmental mobility and function in enzymes are thought to be particularly closely related. Due to the large number of sites that may be distinguished in proteins, the sensitivity and site resolution of CODEX is indispensable for studies of slow motions. Hong and coworkers have introduced ^{13}C -detected ^{15}N CODEX for studies of slow motions in ^{13}C -labeled globular proteins.⁵⁰ In a triblock protein hydrogel, the experiments revealed large-amplitude reorientations of the α -helical segments that form the reversible cross-links.⁵⁷

7 OUTLOOK

7.1 Perspective on CODEX, PUREX, and 2D Exchange Spectra

Overall, CODEX is complementary to detailed 2D exchange NMR studies without sample rotation. The CODEX MAS approach makes it easy to identify groups with interesting dynamics, characterize their correlation times, estimate the motional amplitude, obtain information on the mobile fraction and the number of accessible sites, and identify simple jumps or more complex motions. The lineshapes of 1D PUREX spectra, which can be regarded as CODEX without sample rotation, can give valuable hints about the motional geometry.²⁵ Given enough interest, these sites can then be isotopically labeled by ^2H or ^{13}C to determine the details of the reorientation process by 2D and 3D exchange NMR; the information on the reorientation angle that is contained in 2D exchange patterns is still unparalleled, in particular for distributions of reorientation angles, and for large reorientation angles.¹

7.2 Summary

Detailed analysis of slow dynamics in complex solids is enabled by centerband-only detection of exchange (CODEX), which combines chemical-shift recoupling by 180° -pulses with exchange NMR. The analysis in terms of the chemical-shift difference tensor explains the surprising sensitivity of the experiment to small-amplitude motions. For uniaxial interactions ($\eta = 0$), this can be expressed by a simple analytical relation. The number of orientational sites accessible to the mobile segments and the fraction of mobile units are reflected in the long-time exchange intensity. Jumps and diffusive motions are distinguishable from the effect of mixing

time on the recoupling-time dependence of their exchange intensity, which reflects the characteristic changes of the reorientation-angle distributions. Pure-exchange CODEX can also be used as a dynamic filter to observe slow-moving groups selectively.

1 INTRODUCTION

There are a number of methods in solid state NMR spectroscopy which can be used to obtain information about the chemical shift tensor. The method of choice is usually a function of the equipment available, the complexity of the sample, the information desired, and the state of the sample at ambient temperatures. This article serves as an overview of the various methods, and deals with the requirements and limitations in terms of both sample and instrumentation for each technique, as well as with the information that can be obtained. A more detailed description for some of these techniques can be found in other portions of the Encyclopedia, as listed in Section 10. It should be noted that no effort is made to include listings of chemical shift tensor data that have been measured. The reader is referred to compilations of this type of data, the most recent being Duncan's book.¹

Before the description of the methods, a brief introduction concerning the Zeeman interaction, chemical shielding, dipolar coupling, and quadrupolar interactions that must be considered is presented. Again a more detailed discussion concerning these interactions is presented elsewhere in this Encyclopedia or can be obtained from a number of books.²⁻⁵

2 MAGNETIC INTERACTIONS

2.1 Zeeman Interaction

In the presence of a magnetic field, a nucleus possessing a spin ($I \neq 0$) will be in one of $2I + 1$ energy levels, defined by the magnetic moment of the nucleus and the strength of the static magnetic field, B_0 . The NMR experiment measures the transitions between these levels. The direction of the applied magnetic field is taken by convention to be along the

z direction, and the difference in energy between any two of the allowed states, in frequency units (Hz), can be given as

$$\nu_0 = \gamma_I B_0 / 2\pi \quad (1)$$

This frequency ν_0 is known as the Larmor frequency, and is a function of the field strength and the magnetogyric ratio, γ , of the nucleus.

2.2 Chemical Shielding

The chemical shielding interaction separates the resonance frequencies of nuclei based on their electronic environment. The magnetic field experienced or 'seen' by the nucleus of an atom in a molecule is affected by the electrons that surround that nucleus. The chemical shift tensor is a reflection of this orientation-dependent interaction of the electronic environment of a nucleus with the external magnetic field. In general, a different value of the chemical shift will be observed for a nucleus for each orientation of that molecule in the magnetic field. The dependence of the chemical shift on the molecular orientation will be further elaborated upon in the next section.

In the most general terms this chemical shift interaction is represented by a 3×3 Cartesian matrix,

$$\delta = \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{xz} \\ \delta_{yx} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{zy} & \delta_{zz} \end{bmatrix} \quad (2)$$

The interaction can be decomposed into three parts: the isotropic, the symmetric, and the antisymmetric portions,

$$\delta = \delta_{\text{iso}} + \delta_{\text{sym}} + \delta_{\text{anti}} \quad (3)$$

The isotropic matrix gives the position of the center of the spectrum, while the symmetric matrix defines the lineshape observed. The antisymmetric portion has no observable effect on the lineshape, at the current level of technology and will not be further considered in this work. Often the first two terms are combined and given as

$$\delta = \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{xz} \\ \delta_{xy} & \delta_{yy} & \delta_{yz} \\ \delta_{xz} & \delta_{yz} & \delta_{zz} \end{bmatrix} \quad (4)$$

The resonance frequency that is observed in high-resolution NMR spectroscopy is one-third of the trace of the matrix shown in equation (4), or $\delta_{\text{iso}} = (\delta_{xx} + \delta_{yy} + \delta_{zz})/3$.

There exists some frame in which the matrix in equation (4) is diagonal; in this case the three diagonal elements are known as the principal values of the chemical shift tensor (or tensor components), and are designated as δ_{11} , δ_{22} , and δ_{33} . Convention states that $\delta_{11} \geq \delta_{22} \geq \delta_{33}$, with δ_{11} being in the high-frequency or least shielded direction. The remaining three terms are the Euler angles which define the directions of these principal values in the molecular frame. The axis system in which the symmetric chemical shift matrix is diagonal is known as the principal axis system (PAS).

2.3 Dipolar Coupling

Interactions also exist between magnetic nuclei. The interaction of two spins through space is known as a direct or dipolar coupling. This interaction has a $1/r^3$ dependence on the separation of the two spins and a linear dependence on the γ values of the two spins involved, as shown in equation (5) for the general case of two different spin- $\frac{1}{2}$ nuclei, I and S , e.g., ^{13}C and ^1H .

$$D = \frac{\gamma_I \gamma_S \hbar}{r_{IS}^3} \quad (5)$$

The dipolar interaction is also orientation-dependent; in this case the tensor is axially symmetric and has a trace of zero. The fact that the dipolar tensor is traceless means that the dipolar interactions average to zero in high-resolution NMR spectra. The unique component of the dipolar tensor is along the vector connecting the two spins, generally designated as D_{zz} and is equal to $2D$, and the two identical components, D_{xx} and D_{yy} , with the value of $-D$, are in the plane perpendicular to this vector.

In the case of solid state NMR studies of organic compounds, most typically carbon is the nucleus of interest. Only 1.1% of all carbon nuclei are ^{13}C , which is the magnetic isotope of carbon. The remainder of the carbon nuclei have no magnetic moment and as such are nondetectable. For this reason, dipolar couplings between directly bonded carbons only occur in approximately one of every 10 000 pairs. Magnetic isotopes of low natural abundance, such as carbon, are said to be 'rare' or dilute spins. This is also the case for a number of other nuclei, with ^{15}N being a second important case of a rare spin. However, as more than 99% of all hydrogen nuclei are protons (^1H) with $I = \frac{1}{2}$, dipolar couplings both between protons and between the rare spins and the protons play an important role in organic compounds. These ^1H - ^1H and ^1H - ^{13}C dipolar interactions are very large (tens of kHz) and can completely obscure the chemical shift information. Fortunately, these interactions can be removed by a technique known as proton dipolar decoupling, which is the use of irradiation at the proton frequency during the observation period. Decoupling can be used to remove unwanted dipolar interactions in all cases where the rare spin being observed is coupled to an abundant spin system.

There are also several decoupling schemes that remove the dipolar interactions between nuclei of an abundant spin while allowing for the observation of the chemical shift information of that same spin. These techniques are grouped together as multiple pulse decoupling techniques,⁶ and are most commonly used when observing ^1H or ^{19}F .

Finally, dipolar couplings between two (and occasionally three or more) spins can be used to obtain information about both the orientation of the PAS and the distance between the spins. A molecule can be selectively enriched with two magnetic isotopes to achieve an isolated spin pair; alternatively, compounds can be enriched in one position and the second spin of the dipolar pair can be one of high natural abundance, but uncommon (^{19}F or ^{31}P), or a spin- $\frac{1}{2}$ pair may exist naturally (^{31}P - ^{31}P).

2.4 Quadrupolar Effects

For the quadrupolar nuclei, i.e. those with spins ≥ 1 , the observed lineshape is typically dominated by the nuclear quadrupole interaction, given for a spin I in equation (6):

$$\mathbf{Q} = \frac{eQ}{2I(2I-1)\hbar} \mathbf{V} \quad (6)$$

Again the interaction is anisotropic, with the factor eQ being the quadrupole moment and $\mathbf{V}$ the electric field gradient (EFG) tensor. The EFG tensor has a PAS just like the chemical shift tensor; the EFG tensor is traceless, and does not appear directly in liquid spectra due to rapid, isotropic molecular tumbling in solution. The quadrupole coupling constant, $\chi = e^2 Qq/h$, ranges from 100 kHz to tens of MHz depending on the nuclei (i.e., ^2H , ^{14}N , or ^{17}O) and the symmetry about the nuclei.

Due to the fact that quadrupolar coupling terms are usually orders of magnitude larger than the span of the chemical shift values, the lineshapes obtained are typically only fitted using the isotropic chemical shift along with the quadrupolar parameters. Therefore, the principal values of the chemical shift tensor have only been obtained for a small number of quadrupolar nuclei.¹ Due to this lack of reported measurements of the principal values, no further discussion on quadrupolar nuclei will be presented in this article.

When quadrupolar nuclei are coupled to spin- $\frac{1}{2}$ nuclei, there exists a dipolar coupling; this situation will be included in the section on dipolar spectra.

3 EXPERIMENTAL CONSIDERATIONS

3.1 Cross Polarization

The first step in all the experiments that will be discussed is to take the magnetization of the spin of interest from its equilibrium position, aligned with the magnetic field, to the xy plane. This is commonly done using one of two methods: by application of a 90° pulse (also known as a Bloch decay or BD) or by cross polarization (CP).⁷

The experiment of choice is typically CP, in which the signal of the low abundance spin system is enhanced via magnetization transfer from a second magnetic nucleus which has both a higher natural abundance and a higher γ value. Again the most common nucleus used for magnetization transfer is the proton. The CP method has two advantages over BD: there is a signal enhancement of the rare spin by up to a factor of the ratio of the γ value of the high abundance spin to that of the rare, lower γ spin, and the relaxation times, which dictate how fast a repetition rate can be used in the signal averaging process, are typically faster for the more abundant spin.

In the BD experiment, a 90° pulse is used to take the magnetization of the spins directly into the xy plane, followed by an observation period during which the decay of magnetization in this plane as it returns to its equilibrium position along the magnetic field direction is recorded. The BD experiment is used in cases without an abundant spin system, i.e. systems without protons.

In order to obtain signals from only protonated carbons or signals from only nonprotonated carbons, the techniques of short CP or contact times (SCT) and dipolar dephasing (DD) can be used.^{8,9} With short contact times (about 40 μ s), only carbons with directly bonded protons develop magnetization, resulting in a spectrum containing only signals of these carbons. With DD, time is allowed for magnetization transfer to develop to all carbons, followed by a period during which the magnetization of the strongly coupled spins, i.e. the protonated carbons, is allowed to decay. The magnetization dephasing is much slower for the weakly dipolar-coupled (nonprotonated and mobile methyl carbons) spins. After this dephasing period a normal acquisition shows only signals from these weakly dipolar-coupled carbons.

3.2 Magic Angle Spinning

Magic angle spinning (MAS)^{10,11} is a technique used in conjunction with high power decoupling to obtain high-resolution or solution-like spectra from a solid powder sample. With MAS the chemical shift interaction is averaged to its isotropic value and dipolar interactions are removed by rapid rotation of the sample at an angle of 54.7°, the magic angle, with respect to the B_0 . The average chemical shift δ of a given nucleus in a sample that is rotating about an angle θ with respect to the external magnetic field is given by

$$\begin{aligned} \delta = & \delta_{\text{iso}} + \frac{1}{2}(3 \cos^2 \theta - 1) \\ & \times \left[\frac{1}{2}(3 \cos^2 \beta - 1)(\delta_{33} - \delta_{\text{iso}}) \right. \\ & \left. + \frac{1}{2} \cos^2 \beta \cos 2\alpha(\delta_{11} - \delta_{22}) \right] \end{aligned} \quad (7)$$

where α and β are two of the three Euler angles which specify the orientation of the PAS in the frame of the spinning system, and the δ quantities are the various elements of the chemical shift tensor. At $\theta = 54.7^\circ$, the term $(3 \cos^2 \theta - 1)$ is zero, and the pattern collapses to a single line at the frequency given by the isotropic chemical shift, δ_{iso} , provided that the rotation frequency, ω_r , is larger than the width of the powder pattern.

4 SAMPLES: POWDERS VERSUS SINGLE CRYSTALS

4.1 Powder Samples

So-called powder techniques (both one- and two-dimensional) are performed on powdered or microcrystalline samples, or on samples that have molecules in a statistical distribution of all possible orientations with respect to the magnetic field. The principal values of the chemical shift tensor define the spectral lineshape obtained for the case of a decoupled spin- $\frac{1}{2}$ nucleus. The resultant lineshapes as shown in Figure 1 can be used to obtain the principal values of the chemical shift tensor. The change in intensity across the powder pattern can be explained by representing the chemical shift as an ellipsoid centered at the nucleus. The distance from the center to the outside of the ellipsoid represents the magnitude of the chemical shift with the static magnetic field in that direction while the three axes of the ellipsoid are the directions giving rise to the three principal values. While there are only two directions which give

Figure 1 Examples of chemical shift powder patterns for one spin- $\frac{1}{2}$ nucleus: (a) symmetric system, (b) axially symmetric system, and (c) general asymmetric tensor. Arrows indicate the position of the principal values of the chemical shift tensor

rise to each of the three principal values there are multiple directions that give rise to the values between the principal values.

For the case of nuclei with highly symmetric electronic environments, for example the carbon in methane, CH_4 , the electronic environment does not change as a function of the orientation of the molecule in the magnetic field, and thus the chemical shift is the same in all orientations. This situation occurs when the symmetry at the nucleus is tetrahedral or greater and gives rise to an isotropic chemical shift powder pattern, shown in Figure 1(a), where the three principal values are all equivalent and equal to the value observed in high-resolution NMR spectroscopy. The entire width of the powder pattern is due to residual broadening effects.

The next case is where two of the three principal values are equivalent (known as an axially symmetric tensor) which occurs in cases where there is a threefold symmetry axis through the nucleus, e.g. N of NH_3 . The unique principal value lies along the threefold axis and is designated $\delta_{\parallel}$ while the degenerate components are in the plane perpendicular to the axis and are designated $\delta_{\perp}$. These two values can be read from the extremes or breakpoints of the powder pattern, as indicated in Figure 1(b).

The most general case is when the symmetry elements present at the nucleus are all less than threefold, resulting in all three of the principal values being different, as shown in Figure 1(c). In general, only the three principal values of the

chemical shift tensor can be measured from a powder sample. However, in some cases, the symmetry of the molecule at the nuclei of interest can indicate the directions of one or more of the principal values of the tensor (but not which principal value is in that direction). The more the electronic environment varies, the broader the powder pattern.

The techniques that can be used to obtain the principal values of the chemical shift tensor for decoupled spin- $\frac{1}{2}$ nuclei using a powder sample are divided into two broad categories: the one-dimensional (1D) methods, discussed in Section 5, and the two-dimensional (2D) methods, covered in Section 6.

4.2 Single Crystals

In a single crystal there is no longer a distribution of all possible orientations with respect to the external magnetic field as in a powder sample. Instead of seeing broad powder patterns which are independent of the orientation of the powder sample in the magnetic field, the NMR signal from a single crystal placed in a magnetic field is a series of narrow lines, one for each magnetically inequivalent nucleus. When the crystal is rotated, the position of these lines change. The manner in which the position of a given line in the spectrum changes as a function of the crystal orientation in the magnetic field, again for decoupled spin- $\frac{1}{2}$ nuclei, is given by the expression

$$\delta = \delta_{11} \cos^2 \alpha \sin^2 \beta + \delta_{22} \sin^2 \alpha \sin^2 \beta + \delta_{33} \cos^2 \beta \quad (8)$$

where α and β are the Euler angles which relate the PAS to the magnetic field direction. Knowing the crystallographic orientation of the single crystal as mounted in the NMR probe, this information can be used to determine the orientation of the PAS in the molecular frame.

Aside from the advantage that the entire chemical shift tensor is determined, a second advantage is that single crystal NMR data are the most precise. The estimated errors in the principal values are in the order of 1 ppm or less, whereas the errors in the powder techniques are generally in the range of 3 ppm or more. Intermolecular interactions and/or structural distortions in crystals can lead to very small shifts in these principal values and/or orientations between two nuclei, and these effects, while immeasurable by powder techniques, can be observed by single crystal NMR.¹²

While this experimental method provides the most information, it is also the method with the most limitations. The most severe limitation is that a relatively large single crystal (several mm in all dimensions) of the compound of interest must be obtained, a feat not always possible. This automatically limits the possibilities to room temperature solids from which single crystals can be grown and transferred into the NMR probe. However, if a suitable crystal can be grown, it is the method of choice.

Single crystal studies have been completed on dilute spin systems, mainly ^{13}C , as well as on abundant spins such as ^1H or ^{19}F . For ^{13}C , the cross polarization method in combination with high-power proton decoupling is used; for the abundant spins, multipulse decoupling techniques are necessary.

Just as the powder techniques are divided among 1D and 2D methods, so are the single crystal methods. In Section 7, the experimental techniques for obtaining the chemical shift information from a single crystal will be presented.

5 ONE-DIMENSIONAL POWDER TECHNIQUES

5.1 Static Powder Sample

The simplest, most straightforward experimental method for obtaining the principal values of the chemical shift tensor is to record the spectrum of a static solid sample and measure the principal values from the breakpoints in the powder pattern, as indicated in Figure 1.² The sample can be a solid without any molecular reorientation at room temperature, or it can be a sample at a temperature low enough both to take the sample into the solid state and to stop any molecular reorientation. Most typically, the CP technique in conjunction with high-power decoupling is used to obtain the powder pattern of common, low natural-abundance spin- $\frac{1}{2}$ nuclei such as ^{13}C or ^{15}N or a high natural-abundance, but uncommon, nucleus such as ^{31}P . Powder patterns can also be obtained for common, high natural-abundance spin- $\frac{1}{2}$ nuclei (e.g., ^1H) with the use of multiple pulse decoupling techniques.

The use of static powder samples has one severe limitation. In molecules containing several nonmagnetically equivalent nuclei, e.g., several different carbons, overlap between the powder patterns can make the determination of the principal values impossible. This is demonstrated by the powder pattern of 1,2,3,6,7,8-hexahydropyrene, given in Figure 2 along with the best fit to the lineshape due to the aromatic carbons. In this case there are three magnetically inequivalent aromatic carbons, with the powder patterns labeled A, B, and C in the decomposed simulation. The portion of the spectral lineshape not fitted is due to the aliphatic carbons.

Even though there have been numerous techniques introduced which help to overcome this limitation concerning sample complexity, the use of a static powder sample is still very common as it is the only technique applicable for certain samples. While variable temperature probes could, in theory, be built to perform many of the experiments that will be discussed below, the majority of the probes that have been built for these techniques can only handle room-temperature solids. On the other hand, it is fairly simple to equip a NMR probe for a static sample with variable temperature capabilities to solidify a liquid and perform a static powder measurement on the sample.

NMR probes have also been constructed to interface with closed cycle cryogenic units, capable of reaching temperatures as low as 4 K.^{13,14} This allows the study of not only samples that are liquids or gases at room temperature, but also molecules isolated in an inert environment. Molecules not stable under normal conditions for any reasonable length of time can be generated and quickly deposited on the cold tip of the cryogenic unit, or molecules can be generated photochemically after deposition of a precursor species. For these situations, the only option for obtaining any information on the principal values of the chemical shift tensor is to measure a static powder pattern.

5.2 Variable Angle Sample Spinning

The problem of overlapping tensor patterns can be somewhat alleviated by partially averaging the lineshape by spinning the sample at an angle other than the magic angle, a technique

Figure 2 Static powder pattern of 1,2,3,6,7,8-hexahydropyrene with best-fit simulation of the aromatic region. Simulation is decomposed into the three components, where A is the lineshape of the substituted aromatic carbons, B is the pattern of the condensed or bridgehead aromatic carbons, and C is the pattern of the protonated aromatic carbons. (Reproduced by permission of the American Chemical Society from N. K. Sethi, R. J. Pugmire, and D. M. Grant, *Prepr. Am. Chem. Soc., Div. Fuel Chem.*, 1987, **32**, 155)

known as variable angle sample spinning or VASS.^{15,16} As described in Section 3.2, if a sample is spinning at an angle of 54.7° relative to the external magnetic field, and the spinning rate is greater than the width or anisotropy of the pattern, each pattern is collapsed to a relatively narrow line at the isotropic chemical shift, according to the expression in equation (7). If the chosen angle is not the magic angle then the pattern is scaled by the $3 \cos^2 \theta - 1$ term, where the angle between the spinning axis and the external magnetic field is given as θ . For angles less than the magic angle the pattern is scaled, and for angles greater than the magic angle the pattern is inverted about the isotropic chemical shift as well as scaled. Representative VASS spectra of 1,2,3,6,7,8-hexahydropyrene are shown in Figure 3 for four different angles. It should be noted that the powder pattern for each individual spin is scaled differently, and therefore the resultant patterns are not just scaled versions of one another but are distinctive lineshapes. Experimentally, it has been demonstrated that recording five spectra, one at the magic angle and four at other angles, and simultaneously fitting the four off-angle spectra while locking the isotropic values to those obtained by the magic angle spectrum, gives good results.¹⁷

One of the major advantages of the VASS technique is that it removes the overlap that is nearly always observed between the δ_{33} component of unsaturated carbons and the aliphatic carbon

Figure 3 VASS powder patterns of 1,2,3,6,7,8-hexahydropyrene taken at specified angles θ with respect to the static magnetic field direction, along with best fit simulations of the aromatic region. signals. Also, less time is required to obtain a spectrum with the same signal-to-noise (S/N) ratio as a static powder pattern due to the scaling of the powder pattern. Because a number of different spectra can be recorded and fitted simultaneously, the number of tensors that can be fitted is slightly increased relative to the number of tensors that can be obtained from a static powder pattern.

5.3 Slow Magic Angle Spinning

Another method that can be used to alleviate the problem of overlapping powder patterns is to spin at the magic angle but at speeds less than the width of the patterns, a technique that is known as the Herzfeld–Berger method.^{18,19} The resulting spectrum is a series of narrow lines spaced about isotropic chemical shift at integer multiples of the spinning speed for the width of the powder pattern, as shown in Figure 4(b) for the carbons in 1,2,3-trimethoxybenzene. Combining this spectrum with the spectrum taken at a higher speed MAS, shown in Figure 4(a) for 1,2,3-trimethoxybenzene, the center or isotropic chemical shift peaks can be identified, and the various sidebands can then be matched to the proper centerline. The intensities of these spinning sideband (ssb) patterns can

Figure 4 (a) MAS spectrum of 1,2,3-trimethoxybenzene (shown in inset) at a spinning rate of 6.0 kHz. (b) Spinning sideband pattern obtained for 1,2,3-trimethoxybenzene at a spinning rate of 1106 ± 5 Hz

then be analyzed by several methods to yield the principal values of the chemical shift tensor.

This procedure has not been used very widely as it requires a careful measurement of the integrated intensities and the use of a more complex analysis than needed for static patterns, and the errors in the principal values obtained from this technique are typically greater than those from the other methods. Experimentally, it is crucial that the spinning speed be constant (± 10 Hz); however, with modern spinning speed controllers this is very feasible. The limitation in the number of magnetically inequivalent spins is determined by the width of the lines; if a compound contains several spins with similar isotropic chemical shifts, overlap can prevent accurate line intensities being obtained.

More recently, the Herzfeld–Berger method has been combined with DANTE pulse sequences²⁰ to saturate selectively one or more of the ssb patterns to simplify the spectra of complex compounds.²¹ After the initial preparation of magnetization by a normal CP sequence, a DANTE sequence centered at the frequency of one of the peaks of the ssb pattern to be destroyed is added. This sequence leaves the magnetization of the other spins unaffected. Several DANTE sequences at different frequencies can be added, with the limitation that the spin–lattice relaxation time (T_1) be of sufficient length that the magnetization for the desired spins does not relax back to thermal equilibrium during the time it takes to apply the saturation sequences.

This concept of producing selective 1D spectra can be considered an alternative to the 2D approach of obtaining all

the ssb patterns separated in 2D space, as presented in the section on 2D methods. This same approach is also used in the next section in conjunction with spinning at two different angles.

5.4 Switched Angle Spinning

A one-dimensional version of the 2D switched angle sample spinning (SASS) experiment to be discussed in the next section was introduced in 1990.^{22,23} By combining the principles of switched angle spinning with some type of selective irradiation scheme, a spectrum containing only the powder pattern(s) of the selected spin(s) can be obtained. The magnetization of the selected spin is selectively prepared or inverted with the sample spinning at the magic angle using a technique such as the DANTE sequence in the case of Maciel’s work²³ or selective soft rf pulses as done by Ashida et al.²² It is necessary that spinning be conducted at the magic angle in order to be able selectively to irradiate one spin while not affecting the magnetization of the remaining spins. The spinner axis is then changed to a different angle before the detection period, resulting in a scaled powder pattern containing only the signals of the selected spin. There is, however, a limit to how selective a pulse can be; if there are two or more signals closely spaced, it is impossible selectively to irradiate only one of them.

The experiment was undertaken in a 1D manner in the belief that conducting a number of 1D experiments in such a way as to obtain the spectra of all spins may be more time-efficient than conducting a 2D experiment in some cases. This judgment is very dependent on the nature and number of the nuclei in the sample.

6 TWO-DIMENSIONAL POWDER TECHNIQUES

The various 2D techniques that have appeared in the literature are discussed in this section. However, before discussing the specifics of each technique, some comments general to 2D spectroscopy are necessary. First, all 2D spectral techniques can be described in terms of the preparation of a magnetization period, followed by an evolution time, t_1 , possibly a mixing time, and then an acquisition time, t_2 . The evolution time is increased by a constant time increment between successive spectra in the 2D experiment, and the signal acquired during the acquisition time is a function of both the evolution time and the acquisition time. In all the cases outlined below, the techniques were described for the observation of dilute spin- $\frac{1}{2}$ nuclei, and the preparation period consisted of a normal CP sequence to take the magnetization into the transverse plane. A general 2D pulse sequence, using CP for signal enhancement, is shown in Figure 5.

While these 2D techniques can be divided in a number of ways, in this article the techniques that obtain the isotropic dimension during the evolution time will be discussed first, followed by those which use MAS during the acquisition time to obtain the isotropic information in the second dimension.

As the spectral presentation of the individual powder patterns as ridges in a 2D contour plot, with the projection on the two axes being an isotropic spectrum and a normal powder pattern, is the same in the majority of these techniques, sample spectra are not included for each technique. Instead only one

Figure 5 A schematic representation of the times in a general 2D pulse sequence, along with a typical 2D pulse sequence for both the ^1H (decoupler) and observe nucleus channels, using CP for the preparation of the magnetization. The pulse sequence shown is the basic 2D chemical exchange scheme. The mixing period is optional

representative spectrum of this type is included. Representative spectra obtained for the 2D methods that present the chemical shift information in a different manner are also included. Also, no information is provided on the details of the phase cycling used in the methods; the reader is referred to the original references for this information.

6.1 Magic Angle Hopping

Magic angle hopping (MAH)²⁴ was one of the first 2D techniques which provided isotropic chemical shifts, i.e. a normal MAS spectrum in the first dimension, with the individual powder patterns separated in the second dimension. The MAH experiment is carried out with a static sample at the magic angle with respect to the external magnetic field. The sample is successively hopped by 120° about this axis, using a computer-controlled stepping motor such that the sample spends one-third of the evolution time in each of the three orientations. Between these three periods the prepared magnetization is stored along the magnetic field direction with a 90° pulse; the sample is reoriented or hopped, followed by the return of the magnetization to the xy plane with a second 90° pulse. The timing of the pulses and the hopping of the sample during the evolution time are shown in Figure 6(a). As there is no spinning of the sample, the isotropic chemical shift dimension has no spinning sidebands.

The major difficulty in this experiment is the requirement of rapidly and accurately reorienting the sample during each scan. The original work reported a hopping time of 150 ms; subsequently, in a paper reporting several modifications to the original experiment,²⁵ the hopping time was reduced to under 60 ms with the use of a dc servo motor. The shortening of this hopping time is important as the magnetization that is prepared and subsequently stored along the magnetic field by the 90° pulse is decreased by normal T_1 relaxation mechanisms. The accuracy in setting the angles is reflected in how complete the averaging process is, and it therefore affects the width of the lines observed in both the isotropic chemical shift spectrum and in the 2D space, placing a limitation of the resolution obtainable.

The reported modifications of the MAH experiment also included a larger sample volume to allow for the measurement of a 2D spectrum in under 24 h, and an increase in the signal collected in each scan by incorporating the last one-third of the evolution time into the acquisition dimension, as discussed in the next technique.

6.2 Magic Angle Turning

One of the most recent 2D techniques for the separation of the overlapping powder patterns was introduced by Gan in 1992²⁶ and is known as the magic angle turning (MAT) method. Gan's technique is a very simple method which can, in principle, be undertaken on a normal MAS probe without any additional equipment. The MAT method is based on the fact that continuous, very slow, spinning at the magic angle can be used in place of the three discrete 120° hops in the MAH experiment. Instead of mechanically hopping the sample by 120° , Gan proposed that the pulses in the evolution period be separated by a time equal to one-third of the rotor period, as shown in the pulse sequence in Figure 6(b).

A second modification from the previous MAH method is that the acquisition period was started immediately after the last pulse instead of waiting a time period of one-third of the evolution period. This modification of acquiring the complete echo instead of starting the acquisition at the top of the echo increases the signal intensity by nearly a factor of $\sqrt{2}$. A consequence of this modification is that the 2D space is no longer a square but has the powder patterns at an angle defined by $\tan^{-1}(1/3)$, and it must be sheared or rotated by this angle in order to obtain normal projections of the isotropic chemical shift spectrum.

This technique was subsequently refined, and the power of the method demonstrated²⁷ using a probe designed specifically for the experiment. The probe, designed around a large volume rotor (about 5 cm^3), has a maximum spinning rate of about 200 Hz, and is very stable at spinning rates as low as 22 Hz. Normal commercial MAS probes, on the other hand, are optimized for stable spinning at speeds in the kHz to tens of kHz range and it is usually difficult to maintain stable spinning at very low speeds. The modification of the pulse sequence, designated the triple echo MAT and shown in Figure 6(c), consists of an addition of three echo pulses to Gan's proposed pulse sequence in order to remove phase imperfections and anomalies in the 2D base plane. The lowered spinning speed also simplifies the fitting of the powder patterns obtained as slices of the 2D space, as they are identical to a static powder pattern at these speeds. It was shown that the spectral lineshape is affected at speeds as low as 44 Hz, requiring that the data be fitted instead of being able to read the break points directly from the lineshape. The large volume sample allows for a typical 2D spectrum to be obtained in less than 24 h, making it feasible for this technique to be used on a routine basis.

This paper also demonstrated that the method can be combined with the techniques of SCT to obtain spectra containing signals from only the protonated carbons, and DD for spectra containing only patterns from nonprotonated carbons. A typical 2D spectrum obtained using the triple echo MAT method, along with the individual powder patterns obtained, is shown in Figure 7 for 2,6-dimethoxynaphthalene, which has six inequivalent aromatic carbons.

6.3 $5-\pi$ Pulse

The $5-\pi$ pulse experiment²⁸ is another method related to the MAT and MAH techniques. In this experiment, as in MAT, the sample is also spinning slowly at the magic angle. However, instead of storing the selected magnetization along

Figure 6 (a) The evolution and acquisition time of the MAH pulse sequence for both the observe and decouple channel. (b) The evolution and acquisition time of the original MAT pulse sequence. (c) The evolution and acquisition time of the triple echo MAT pulse sequence. Δ indicates the echo time. (d) The evolution and acquisition time of the 5- π pulse method. The shaded pulses are the ones which move as a function of the evolution time, τ . For (b)–(d), the decoupler remains on for the entire evolution and acquisition periods. In all cases 0 marks the start of the evolution period, T signifies the length of a rotor period, and a normal CP sequence used to prepare the magnetization

the static field direction during the course of the experiment, the magnetization is kept in the transverse plane and a series of five π pulses are used to achieve the same effect. This method can be thought of as a constant time version of the MAT experiment.

As shown in Figure 6(d), two of the five π pulses are at the fixed times of $T/3$ and $2T/3$ during the evolution period, where T must be an integral number of rotor periods. Each π pulse changes the sign of the phase angle describing the precession of the magnetization up until the application of the pulse. The position of the first, third, and fifth π pulses are set at times $T/6 - \tau$, $T/2 - \tau$, and $5T/6 - \tau$, where τ is the evolution variable which ranges from $-T/6$ to $T/6$. At $\tau = 0$, the five π pulses are evenly spaced at increments of $T/6$, such that the accumulated phase is zero, resulting in the complete suppression of the chemical shift. When $\tau \neq 0$ the pulses are no longer evenly spaced, and the phase accumulation is proportional to $\omega_{\text{iso}}\tau$. Thus, the evolution dimension displays an isotropic chemical shift spectrum. The spectrum in the

acquisition dimension is either a ssb or a static powder pattern depending on the spinning speed used.

This technique has an advantage over the MAH and MAT experiments in terms of increased sensitivity by avoiding the need to project the magnetization to the longitudinal direction. However, the 5- π pulse method does suffer from a loss of signal at longer evolution times (and therefore lower rotation frequencies) if the T_2 value of the spin is short in comparison to the total time T between the preparation of the magnetization and the start of the acquisition period.

6.4 Stop and Go

In the 2D technique known as stop and go or STAG²⁹ the sample, at the magic angle with respect to $\mathbf{B}_0$, is taken from being stationary during the preparation and evolution of the magnetization to high speed spinning during the acquisition period, as shown in the pulse sequence used in Figure 8(a). The

Figure 7 (a) A 2D MAT spectrum of 2,6-dimethoxynaphthalene (shown in inset). (b) The projection in the isotropic chemical shift dimension. (c) The individual powder patterns taken from the 2D spectrum in (a) at the indicated isotropic chemical shifts

air used for spinning is controlled with a solenoid valve that is electronically opened and closed by the pulse programmer controlling the NMR experiment. At the end of the evolution period the magnetization is stored along the magnetic field, in the manner discussed in the previous 2D methods, the air flow is started, and the sample is allowed to come to a relatively high spinning speed. Once the desired spinning speed has been

reached, the stored magnetization is returned to the xy plane for detection. In the original paper the time required to start the spinner and achieve a spinning speed of 1.7 kHz was in the range of 3–5 s.

The spectra obtained are identical to those of the original MAH spectrum, with the exception that there are now spinning sidebands observed in the spectra as the sample is spinning

Figure 8 The 2D pulse sequence used in the STAG, S^3 , and SAS 2D experiments. A normal CP preparation period was typically used. The $\pi/2$ pulses store the evolved magnetization along the field direction during the switching time and then return it to the transverse plane. (a) For STAG, the sample is stationary during the preparation and evolution periods and is spinning at the magic angle during the acquisition period. (b) In S^3 , the spinning speed is increased by a factor of 5–10 during the mixing time. (c) In SAS, the spinning speed remains constant but the spinner axis changes relative to the external magnetic field. The length of time taken to accomplish these changes (the length of the switching period) is discussed in the text

during acquisition. The limitations of this method are also the same; namely this approach is only applicable to spin systems with T_1 relaxation times long compared with the time taken to bring the sample from the static condition to the maximum spinning speed.

6.5 Switched Speed Spinning

The switched speed spinning (S^3)³⁰ experiment is similar to that of the STAG method except that the spinning speed is only reduced by a factor of ca. 5–10 during the preparation and evolution time of the 2D experiment instead of being completely stopped, and is shown in Figure 8(b). The experiment was performed on an unmodified MAS probe using a commercially available spinning system and the spinner speed was controlled by a system which delivered a flow rate of air proportional to an applied voltage, with the change in this voltage being under the control of the NMR pulse programmer. This results in the anisotropic information being in the form of an ssb pattern instead of a static powder pattern. The fact that the spinning speed is only reduced and not completely stopped should be less demanding on the spinning system.

6.6 Switched Angle Spinning

The next technique has been discussed in the literature under two different names: dynamic angle spinning (DAS) and switched angle spinning (SASS). The method was introduced independently by two different groups shortly after the

introduction of the MAH experimental technique.^{31,32} This technique also requires reorientation of the sample, however this time a rapidly spinning sample is taken between the magic angle and a second angle during each scan, as shown in Figure 8(c).

In this technique the sample is held at the magic angle during the evolution period of a 2D experimental scheme. The evolved magnetization is then stored along the static magnetic field while the spinning axis is changed from the magic angle to any other angle. Following the angle switch, the stored magnetization is returned to the transverse plane for detection. The second angle used can be any other angle, resulting in patterns that are scaled by the argument $\frac{1}{2}(3 \cos^2\theta - 1)$ according to equation (7).

The initial papers on this technique employed switching times on the order of 0.5–2 s. There is now a commercial probe available for SASS measurements with angle switching times on the order of 100 ms, allowing for more widespread use of this method.

Subsequent development of SASS has led to two methods which shorten the time required for the measurement of the chemical shift tensor information. The first involves a technique by which the second dimension, the dimension containing the anisotropic information, can be shortened.³³ In the initial experiment, as in all of the 2D methods discussed, one dimension contains the isotropic chemical shifts and the other contains the separated powder patterns. The projection of the 2D space onto the axis in the second dimension will result in the static powder pattern, as this dimension contains not only the anisotropic information but also the isotropic, i.e. the powder patterns are still offset from each other by the difference in their isotropic chemical shift. However this offset can be removed, resulting in all of the powder patterns being centered at the same frequency. This allows the spectral width in the second dimension to be shortened from that necessary to observe the normal static powder pattern to a spectral width set by the widest of the separated, scaled powder patterns.

The second method introduced to shorten the time necessary to obtain the chemical shift information was the use of the SASS principle in conjunction with selective irradiation or inversion in a 1D experiment,^{22,23} as discussed in Section 5.4.

6.7 TOSS–Reverse TOSS

The TOSS (Total Suppression of Spinning Sidebands) sequence was originally introduced by Dixon et al.^{34,35} to suppress spinning sidebands in normal MAS spectra, resulting in a spectrum containing only the centerband frequencies. The TOSS sequence consists of a series of four π pulses, applied at precise fractions of a rotor period which allow the intensities of the centerband to add while the magnetization of the sidebands are canceled. This technique improves spectral resolution and simplifies MAS spectra, especially those taken at high fields or at low spinning speeds. However, the price is that information about the anisotropic portion of the chemical shift tensor is lost.

However, the anisotropic information can be restored in a 2D experiment by following a normal TOSS sequence with an evolution time and then applying the ‘mirror image’ of the TOSS sequence to reverse the averaging before the start of the acquisition period. The TOSS–reverse TOSS pulse sequence³⁶

Figure 9 (a) The observe channel portion of 2D pulse sequence used in the TOSS–reverse TOSS technique. The separation between the π pulses is discussed elsewhere.^{34–36} (b) The observe channel portion of 2D pulse sequence used in the synchronous application of π pulses with MAS method. The spacing of the four π pulses has been discussed by Tycko et al.⁴⁰ The rotor period is equal to τ . The decoupler remains on during the evolution and acquisition times in both sequences

is shown in Figure 9(a). The sample is spun at the magic angle at a relatively slow rotation frequency. During the evolution period, the effect of the TOSS sequence is such that the magnetization is evolving, containing only the isotropic information, without sidebands, while after the reverse TOSS sequence is applied the evolution once again contains the anisotropic information in the form of an ssb pattern. This information is then collected during the acquisition dimension.

6.8 Magic Angle Spinning with Synchronous Application of rf Pulses

The synchronous application of rf pulses during a MAS experiment in order to reconstruct the anisotropic information averaged by the spinning was first introduced by Lippmaa et al.³⁷ Subsequent improvement³⁸ led to the application of a train of six π pulses per revolution of the spinner in a 1D experimental format and the adaptation of the method to a 2D experiment utilizing four 2π pulses per rotor cycle to decrease the sensitivity of the experiment to pulse imperfections.³⁹ However, in none of the above do the breakpoints in the lineshapes correspond directly to the principal values of the chemical shift tensors, and the reported principal values are not in close agreement with those obtained by other techniques.

Tycko et al.⁴⁰ modified the basic method to render the intensities of the powder patterns obtained in the 2D space undistorted, making the measured principal values of the tensor more reliable, using a series of four or six π pulses as shown in Figure 9(b). The spacing of the four or six π pulses was chosen such that the isotropic scaling factor was zero.

This method, unlike many of the other 2D methods such as MAH, STAG, and SASS, is not demanding mechanically. Instead, the experiment can be performed on a normal MAS probe on a spectrometer system equipped with the ability to synchronize the application of the pulses with the spinning. However with this method it is more difficult to obtain very accurate principal values, due to the sensitivity of the technique to both the timing and quality of the rf pulses. This technique, along with the TOSS–reverse TOSS and the $5-\pi$ pulse method, also does not suffer from the loss of signals from nuclei with shorter T_1 relaxation times.

6.9 Chemical Shift–Chemical Shift Correlation

Chemical shift–chemical shift correlation (CS–CS) spectroscopy⁴¹ is a modification of the 2D exchange NMR experiment,⁴² using the basic pulse sequence shown in Figure 5 in which the stationary sample is reoriented by 90° along an axis perpendicular to the external magnetic field during the mixing time of the experiment. The projections in either dimension give the powder pattern of the sample in each of its two orientations relative to the external magnetic field. For a random powder sample, these two projections are identical. The 2D space, however, contains a unique representation of each tensor in the shape of a triangle for an axially symmetric tensor or a hexagon for a general asymmetric tensor, with the position of the corners defined by the principal values of the tensor. These shapes can be understood by considering the case of a single molecule. In the case of an axially symmetric tensor, if the molecule is in a position with respect to the external magnetic field such that its chemical shift is $\delta_{\parallel}$, then a 90° rotation of this molecule must give a chemical shift of $\delta_{\perp}$. Likewise, if the signal in the first orientation is at $\delta_{\perp}$, after a 90° rotation it must be either $\delta_{\parallel}$ or $\delta_{\perp}$, resulting in the triangular pattern observed in the 2D space. For the case of an asymmetric tensor, a 90° rotation from an orientation which has a chemical shift of any one of the three principal values must take the molecule into an orientation that has a chemical shift of either one of the two remaining principal values, creating a hexagonal pattern in the 2D correlation space.

One of the applications of this method is in sorting out the principal values of overlapping powder patterns, as is demonstrated for coronene in Figure 10. Coronene has

Figure 10 Contour plot of the 2D CS–CS correlation spectrum of coronene (shown in inset)

three magnetically inequivalent sets of carbons. At room temperature the molecule is rotating rapidly about an axis perpendicular to the plane of the molecule, averaging all

the three tensors to axial symmetry. From the normal 1D powder pattern (the projection on either axis) and the isotropic chemical shifts obtained from a MAS spectrum, it is difficult to determine which $\delta_{\parallel}$ and $\delta_{\perp}$ should be paired for each of the three tensors. The patterns in the 2D space, however, clearly indicate how the six principal values are paired to obtain the three tensors.

6.10 Variable Angle Correlation Spectroscopy

In this experimental approach, known by the acronym VACS^Y,⁴³ the approach used to separate the anisotropic information is different from the above techniques. The data are not acquired as a typical 2D data set, i.e., with the evolution time being incremented between individual spectra. Instead, the experiment, performed under the conditions of high-speed spinning, involves collecting a series of VASS spectra taken at different angles. Selected intensities of the signal as a function of time and the spinning angle are then chosen to create a 2D data set for normal 2D FT processing, as shown schematically in Figure 11.

Figure 11 Representation of the strategy employed for obtaining 2D VACS^Y data. The arrows represent the individual FIDs recorded, each at a different spinning axis angle. The grid of points (n_a, n_i) are the points needed for the 2D FT in the acquisition and evolution dimension. Interpolation between the acquired data points is used to obtain signal intensity at all the grid points that fall inside the wedge formed by the minimum and maximum angles. (Reproduced by permission of the American Institute of Physics from L. Frydman, G. C. Chingas, Y. K. Lee, P. G. Grandinetti, M. A. Eastman, G. A. Barrall, and A. Pines, *J. Chem. Phys.* 1992, **97**, 4800)

The dwell time of the VASS spectra is chosen as the time needed in the isotropic direction for sufficient resolution in this dimension. The dwell time in the acquisition dimension is then a function of the range of angles used, and from this information the spinning angles at which spectra are obtained can be calculated. The intensities at certain points in the grid of (n_a, n_i) points shown in Figure 11 are then obtained, using interpolation as necessary; these intensities are then processed using the normal 2D FT methods. Figure 12 shows plots of the different data processing stages in the procedure of obtaining a 2D isotropic–anisotropic chemical shift spectrum of glycine.

Figure 12 Plots of VACS^Y data for glycine ($\text{H}_2\text{NCH}_2\text{COOH}$). (a) Set of 75 FIDs recorded for a grid defined by the dwell time in the isotropic dimension being four times that in the anisotropic dimension. (b) 2D data set after interpolation onto the (n_a, n_i) grid. (c) Spectrum obtained after the 2D FT of data set in (b). (Reproduced by permission of the American Institute of Physics from L. Frydman, G. C. Chingas, Y. K. Lee, P. G. Grandinetti, M. A. Eastman, G. A. Barrall, and A. Pines, *J. Chem. Phys.*, 1992, **97**, 4800)

7 SINGLE CRYSTAL TECHNIQUES

7.1 Crystal Rotation Methods

All the early single crystal studies were undertaken using the 1D crystal rotation method.^{2,3} In this method, the crystal is mounted in the probe on a goniometer. A succession of spectra are recorded with the crystal being rotated by a number of degrees between spectra. This rotation is continued until the sample has been rotated by 180° . The step size used depends on the number of lines and how closely they are spaced; a typical step size is on the order of $5\text{--}10^\circ$. The crystal orientation is then changed by 90° and the process is repeated. Finally the third rotation pattern is obtained for a third axis, perpendicular to the first two rotation axes. A representative rotation pattern of pyrene is shown in Figure 13.

Figure 13 Rotation pattern obtained for one orientation of a single crystal of pyrene (shown in inset). One molecule in the unit cell is sampled nearly in the molecular plane by this rotation; in this case the difference between the in-plane components is small and the lines only move slightly. The other molecule is rotated in and out of the molecular plane and therefore shows a much greater range of chemical shift values as a function of the rotation angle. (Reproduced by permission of the American Chemical Society from C. M. Carter, D. W. Alderman, J. C. Facelli, and D. M. Grant, *J. Am. Chem. Soc.*, 1987, **109**, 2639)

Once the three rotation patterns are obtained, the line positions of each magnetically inequivalent spin must be followed as its position changes from one spectrum to the next, according to the expression given in equation (8). This process can be accomplished in a number of ways, one of which has been to fit the data using a least-squares Simplex fitting routine. Along with the fitting of peaks to different nuclei in one rotation pattern, a connection must be made to the lines in the other two rotation patterns.

Using this method there is a limit to the number of magnetically inequivalent nuclei in the unit cell. As there are more nuclei, the probability that the lines may not all be resolved increases and the large number of line crossings and the crowding often result in rotation patterns that cannot be interpreted, even with small step sizes. This limit has been estimated to be in the range of about 15–20 nuclei and is dependent on the width of the range of chemical shifts for the tensors. As two chemically equivalent nuclei with different orientations in the unit cell will give rise to different chemical shifts, this limitation is very restrictive especially in cases where there is more than one molecule per unit cell.

7.2 2D Crystal Correlation Methods

A 2D technique was introduced in 1985 which allowed for the study of more complex single crystals.^{44,45} This method

is a modification of the Jeener chemical exchange pulse sequence,⁴² with the normal CP sequence for the preparation of the magnetization added. As in the CS–CS method discussed in Section 6.9, the single crystal sample is reoriented during the mixing time of the experiment. This results in a 2D spectrum where the projection onto the axis in one dimension is the spectrum obtained for the first orientation of the crystal, while the projection in the second dimension is the spectrum obtained in the second orientation. In the 2D space there are a number of peaks which correlate a given chemical shift in one dimension (or crystal orientation) with a line position in the second orientation, eliminating the need to determine the best fit in the correlation of the resonance frequencies from one spectrum to the next in a rotation pattern.

In order to obtain all the information contained in a single axis rotation pattern, it has been shown that four 2D correlation spectra are needed. In each of these spectra the two orientations are related by a 45° rotation. The four spectra are taken with the sample between 0° and 45°, 45° and 90°, 90° and 135°, and finally between 135° and 180° (which is 0°). The position of the resonance lines in these four spectra can be connected by placing the four spectra in a square, where the axes corresponding to common crystal position are placed together.

The goniometer used for obtaining rotation patterns is replaced by a device capable of being rotated between two positions using a motor-driven string. The unit has four holes for a lever arm, positioned precisely at 45° increments about the sample. However, the sample must be remounted for each of the three sets of four 2D spectra which are needed for the complete determination of the chemical shift information.

This method was modified in 1989 to include a multiple-axis sample reorientation mechanism⁴⁶ to remove the need for remounting the crystal, as this remounting process introduces errors in the data if the three mounted orientations are not exactly perpendicular. This mechanism is designed to move between any pair of six orientations (X, XY, Y, YZ, Z, and ZX) which were selected such that all the information necessary completely to characterize the chemical shift tensor can be obtained. To determine the chemical shift tensor it is necessary to record only six 2D spectra, corresponding to the X–XY, XY–Y, Y–YZ, YZ–Z, and Z–ZX direction pairs. A representative set of the six 2D spectra is shown in Figure 14 for a single crystal of acenaphthene,⁴⁷ which has four molecules per unit cell with two crystallographically unique molecules. The symmetry of the molecule and the crystal combine to give rise to a total of 36 resonances, which can be analyzed to give the 14 unique chemical shift tensors.

In this figure the connectivity of the peaks due to one of the 14 carbons is shown. The spectra shown in Figure 14 were analyzed to obtain all 28 chemical shift tensors, with a standard deviation of 0.52 ppm between the actual peak positions in the 2D spectra and the expected positions based on the best parameters of the chemical shift tensor. To date, the chemical shift tensors have been obtained for crystals containing up to 72 magnetically inequivalent carbons.

8 DIPOLAR TECHNIQUES

Dipolar couplings can be used to assign the orientation of the PAS to the molecular frame for the nuclei coupled, as well

Figure 14 Set of six 2D multiple-axis reorientation spectra obtained for a single crystal of acenaphthene. The connectivity of peaks for one of the 14 magnetically inequivalent carbons is shown. The labels X, Y, Z, XY, YZ, ZX refer to the directions discussed in the text (Reprinted with permission from R. J. Iulicci et al., *J. Am. Chem. Soc.*, **117**, 2336. Copyright (1995) American Chemical Society)

as to provide information on the separation of the two spins. In practice, this technique is used on compounds which have been specifically labeled in two positions, or in compounds in which there is an isolated pair of spin- $\frac{1}{2}$ nuclei, for an example a ^{31}P - ^{31}P pair. Dipolar couplings also exist between a spin- $\frac{1}{2}$ and a quadrupolar nucleus. The lineshape obtained from a static powder sample containing such a spin pair contains not only the chemical shift information of one (for the case of a heteronuclear dipolar coupling) or both (homonuclear) spins, but also contains information on the orientation of the PAS of the chemical shift tensor with respect to the dipolar vector.

If one were to consider a single molecule in some orientation with respect to the static magnetic field, the chemical shift of a given spin in this molecule specifies the observed line position, that can be designated as ν . If this nucleus were coupled to a second spin, the result would be to see two lines spaced symmetrically about ν , with the separation dependent on D as given by the expression in equation (5) and the position of the dipolar vector. This situation is nicely shown in single crystal studies of compounds containing an isolated spin- $\frac{1}{2}$ pair.

This example can be extended to a spin- $\frac{1}{2}$ pair in a powder sample where the chemical shift of the spins involved is isotropic. In this case the dipolar coupling dominates the lineshape, and a Pake doublet, shown in Figure 15(a), is obtained. The Pake doublet consists of two axially symmetric patterns, with the central peaks being separated by D or $1.5D$ for the cases of heteronuclear and homonuclear spin pairs, respectively.

Now, if the spins have an appreciable anisotropy in their chemical shifts, the lineshape and the analysis of the dipolar pattern is more complicated. A detailed description of the mathematical treatment of the lineshape of dipolar spectra in this case is given in the literature⁴⁸ as well as in a recent review article on dipolar coupling.⁴⁹ Also, more details can be obtained in other sections of this Encyclopedia. For the purpose of this overview, however, the sensitivity of the lineshape relative to this orientation of the vector between the two spins in the PAS of the chemical shift tensor can be

Figure 15 (a) Typical dipolar spectra resulting for the coupling of two spin- $\frac{1}{2}$ nuclei in the absence of any anisotropy in the chemical shift. (b) The dipolar pattern for two spin- $\frac{1}{2}$ nuclei with anisotropy in the chemical shift as a function of the orientation of the internuclear vector with respect to the chemical shift tensor principal axes, where α is the angle between δ_{33} and the dipolar vector, and β the angle between δ_{11} and the projection of the dipolar vector into the plane defined by δ_{11} and δ_{22} . (b) is reproduced by permission of Academic Press from W. P. Powers and R. E. Wayslishen in *Annu. Rep. NMR Spectrosc.*, 1991, **23**, 1

nicely demonstrated with the set of simulated spectra shown in Figure 15(b). The simulations in Figure 15(b) are for the same principal values and dipolar coupling, with only the two angles relating the PAS to the dipolar vector being varied.

As mentioned earlier, a dipolar coupling also exists between a spin- $\frac{1}{2}$ nucleus and a quadrupolar nucleus, and a dipolar spectrum can be obtained by observing the spin- $\frac{1}{2}$ nucleus. The complete chemical shift tensor of the spin- $\frac{1}{2}$ nucleus is obtained, along with the information of the EFG tensor of the quadrupolar nuclei.

Finally, there have been a number of 2D techniques that can be grouped together as separated local field (SLF) techniques, which can provide the chemical shift information in one dimension and information on the dipolar couplings in a second dimension. The SLF technique, first introduced in 1976,⁵⁰ can be used to orient the principal values of a rare spin based on the dipolar coupling between that rare spin (S) and an abundant spin (I), typically a ^1H . In SLF, multipulse decoupling is applied during the evolution time of the 2D experiment to decouple all ^1H - H dipolar interactions, leaving the ^1H - X interactions although they are scaled. The initial experiments were applied to single crystals and to oriented samples.

The basic ideas presented by Waugh were extended to unlabeled static powder samples,⁵¹ with the shape of the spectra in the 2D space containing the information on the PAS; however, with powders, the patterns become very complicated if there are even two different dipolar interactions. The SLF technique has also been used with slow magic angle spinning and has been extended to the determination of the complete chemical shift of a nucleus coupled to two other spins,^{52,53} as well as to being used to extend some of the 2D powder techniques into 3D techniques to gain the information on the orientation of the PAS.⁵⁴

9 SUMMARY

As stated in the Introduction, the method of choice is primarily dependent on the sample. A single crystal study is the method of choice based solely on the amount of information obtained. The more recent 2D multiple axis reorientation method has opened up the field of single crystal studies to systems approaching 100 inequivalent nuclei. However, the limitation in obtaining a suitable sample, i.e., a large enough crystal of sufficient quality, eliminates this method as a choice for a majority of substances.

If a material is a solid at or near room temperature, but one for which a single crystal cannot be obtained, the method of choice is often determined by the equipment available. If there are more than three or four inequivalent nuclei, the experiment of choice will typically be a 2D method. In the last 12 or so years there has been an explosion of 2D and even a few 3D techniques in solid state NMR designed to obtain chemical shift information. While some of these techniques require specialized probes, several can be undertaken on any modern solid state NMR system equipped with a normal MAS probe, provided that only temperatures near ambient are needed. Though some standard MAS probes are capable of reaching temperatures down to 77 K, attaining very low temperatures at high spinning speeds for long periods of times is not easily or economically achieved.

When the sample of interest is a solid only at very low temperatures, or a sample that is stable only at very low temperatures for any reasonable time period, the choices are limited to the 1D techniques which typically take less time. However, samples that are suitable for study by 1D techniques are only the simpler compounds, i.e. those containing only three or four inequivalent nuclei. There have been efforts to use selective techniques, mainly short contact times, to look at only the protonated nuclei, or dipolar dephasing techniques to observe only the nonprotonated nuclei, but these methods have been shown to be of limited usefulness. The alternative is to use compounds selectively enriched at the nuclei of interest and study only that particular spin.

The lowest temperatures can only be achieved with the use of cryogenic equipment which does not allow for sample spinning, limiting the choice to the study of a static powder sample. It should be mentioned that there are several articles in the literature on MAS probes at temperatures in the region of 4 K, but they do not seem to be used routinely and there are no examples, to the knowledge of the author, on the use of such equipment in the study of molecules which are gases at room temperature. With the use of closed-cycle cryogenic units, it is economically feasible to achieve temperatures as

low as 8–10 K on a routine basis. The static sample limits the application of the cryogenic apparatus to studies of very simple cases, or to cases where isotopic labeling has been undertaken. However, this technique is the only method available for the study of reactive species trapped in inert gas matrices, a technique known as matrix isolation. The use of matrix isolation methodology, while very limited in NMR, is more widespread in other forms of spectroscopy.

Finally, for samples where a single crystal study is not possible, but an experimental determination of the PAS orientation is desired, dipolar techniques can be employed. If two dipolar coupled spins exist, or if a sample can be made to contain such a pair using selective enrichment, the orientation of the PAS can be determined for the spins involved. Dipolar spectroscopy has been used at ambient temperatures as well as at cryogenic temperatures.

1 INTRODUCTION

Shortly after its first detection in condensed matter in 1945,^{1,2} it became evident that NMR was an extremely sensitive probe of the local electronic environments of magnetic nuclei. Some of the first observations of NMR uncovered a chemical effect on the relative resonance frequencies of identical nuclear isotopes which has come to be known as the chemical shift, and because of this effect NMR has evolved into one of the premier spectroscopic techniques for chemical structure analysis. The primary use of NMR consists of measuring the isotropic chemical shifts of nuclei imbedded in molecules dissolved in solution; however, important information about the anisotropy of this interaction is available from the spectra of solids.³⁻⁵

Certain characteristics of the anisotropic chemical shift, the principal values of the chemical shift tensor for example, can be obtained from the spectra of powdered samples and, to a lesser extent, from molecules dissolved in liquid crystal solvents. Nevertheless, single crystal samples are preferred, when available, as they allow direct measurements of the complete chemical shift tensor. Single crystals are especially useful for studies of large molecules where the many overlapping powder patterns in traditional one-dimensional (1D) spectra are uninterpretable and where selectively labeling each individual site is impractical. Although progress has been made in extracting principal values from powdered samples of large molecules using two-dimensional (2D) NMR methods,⁶ direct measurements of tensor orientations can be made only on single crystals.

This article is written as an introduction to the techniques that are available for measuring chemical shift tensors in single crystals. Although many aspects of the techniques are quite general, the emphasis here will be on measurements of ^{13}C chemical shift tensors in organic systems.

The first measurement of a ^{13}C chemical shift tensor was made in the very early days of ^{13}C NMR by Lauterbur⁷ on the carbonate ion of single crystal calcite (CaCO_3). This particular sample proved to be ideal because all magnetic nuclei were at

low abundance and thus the dipolar broadening was negligible. A few other systems were exploited where similar dilution occurred naturally or was introduced by substitution of ^2D for ^1H , but progress along these lines was limited. It was only after the introduction of the combined cross polarization and high-power dipolar decoupling techniques⁸ that ^{13}C chemical shift tensor measurements became more generally applicable. One of the first demonstrations of these now widely used techniques was in the measurement of ^{13}C chemical shift tensors in single crystal durene (1,2,4,5-tetramethylbenzene).⁹

2 NUCLEAR SHIELDING AND THE CHEMICAL SHIFT TENSOR

The fundamental equation relating the NMR resonance frequency and the magnetic field strength is well known to all students of magnetic resonance

$$\nu_0 = |\gamma/2\pi|B_0 \quad (1)$$

For ^{13}C , this frequency corresponds to 50 MHz in a typical field of 4.7 T.

Due to the electronic circulation set up in a molecule by the applied magnetic field, the effective field experienced by a particular nucleus is not exactly equal to B_0 . The electronic 'currents' induce a small shielding field B_s which must be added to B_0 to obtain the effective field at the nucleus

$$B_{\text{eff}} = B_0 + B_s \quad (2)$$

This vector addition is shown schematically in Figure 1.

Although B_s is called the shielding field, it does not necessarily oppose B_0 and thus deshieldings or paramagnetic shifts are possible. In general, the direction of B_s is not parallel to B_0 but the two are related through the shielding tensor which is represented as the 3×3 matrix σ

$$B_s = -\sigma \cdot B_0 \quad (3)$$

Figure 1 The relationship between the applied field B_0 , the shielding field B_s and the effective field B_{eff}

The matrix σ is usually called a second rank Cartesian tensor although it also contains zeroth and first rank parts as well.

Since B_s is very small compared to B_0 , equation (2) can be closely approximated by adding only the component of B_s that is either parallel or antiparallel to B_0 to obtain

$$B_{\text{eff}} = B_0 - \frac{B_0}{B_0} \cdot \sigma \cdot B_0 \quad (4)$$

The above approximation is equivalent to *truncation* or restriction to the *secular* terms of the chemical shift Hamiltonian in first-order perturbation theory. It should be pointed out that σ can be decomposed into a sum of second rank symmetric and first rank antisymmetric constituents

$$\sigma = \sigma^S + \sigma^A \quad (5)$$

Since σ^A leads to components of B_s which are perpendicular to B_0 , it does not contribute to B_{eff} in first order and thus its effect on the resonance frequency of the nucleus can be ignored.

The effect of shielding is thus to change the precession frequency of the nucleus from ν_0 to the frequency given by

$$\nu = |\gamma/2\pi| B_{\text{eff}} \quad (6)$$

In practice, the frequency of the bare nucleus is not known, and measurements of the frequency ν are always made relative to a reference frequency ν_{ref} , which for ^{13}C is usually taken as the resonance of liquid tetramethylsilane (TMS). The frequency difference between sample and reference can be written as

$$\nu - \nu_{\text{ref}} = |\gamma/2\pi| \frac{B_0}{B_0} \cdot (\sigma^S - \sigma_{\text{ref}} \mathbf{1}) \cdot B_0 \quad (7)$$

where σ_{ref} is the isotropic chemical shielding constant of the reference compound and $\mathbf{1}$ is the unit matrix. The symmetric difference matrix $(\sigma^S - \sigma_{\text{ref}} \mathbf{1})$ is defined as the chemical shift tensor, and is assigned the symbol δ in order to avoid its confusion with the shielding tensor σ .

It is customary to report chemical shifts not as frequencies, since these always depend on B_0 which varies from one spectrometer to the next, but as fractions of ν_{ref} . If the chemical shift F is defined as $(\nu - \nu_{\text{ref}})/\nu_{\text{ref}}$, then

$$F = \frac{B_0}{B_0} \cdot \delta \cdot \frac{B_0}{B_0} \quad (8)$$

Equation (8) is the master equation for the chemical shift in a single crystal, as it gives the observed shift in terms of the elements of δ and the orientation of B_0 .

For elements with sufficiently low atomic numbers, the chemical shift tensor δ can be represented in a Cartesian coordinate system as a 3×3 symmetric matrix

$$\delta = \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{zx} \\ \delta_{xy} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{yz} & \delta_{zz} \end{bmatrix} \quad (9)$$

The matrix δ is called the Cartesian representation of the chemical shift tensor and is completely defined by

six independent numbers. It will be seen below that other representations are possible.

The average value of δ is known as the isotropic chemical shift

$$\delta_{\text{iso}} = \frac{1}{3}(\delta_{xx} + \delta_{yy} + \delta_{zz}) \quad (10)$$

and it is only this part of the chemical shift tensor which can be directly measured in solution samples due to rapid isotropic tumbling of the molecules. The isotropic chemical shift is also called the zeroth rank part of δ since it transforms as a scalar quantity, i.e., it is invariant under rotation.

A Cartesian tensor can be expressed in a different coordinate system by performing a similarity transformation on the matrix δ

$$\delta' = \mathbf{R} \delta \mathbf{R}^T \quad (11)$$

where $\mathbf{R}$ is a unitary matrix. The element R_{ij} is given by the direction cosine of the i th new coordinate axis with respect to the j th old coordinate axis. For instance, $R_{12} = \cos \gamma_{x'y}$ where $\gamma_{x'y}$ is the angle between the new x axis and the old y axis.

A number of coordinate systems are necessary in single crystal work. The *laboratory frame* is a coordinate system whose z axis lies along the direction of the static magnetic field. Rather than working in the laboratory frame, it is usually more convenient to work in a coordinate system called the *sample frame* whose orientation is fixed with respect to the single crystal sample. The sample frame will always be the coordinate system in which tensors are measured. A third coordinate system is that defined by the symmetry elements of the crystal and this will be called the *crystal frame*. The orientation of the crystal frame relative to the sample frame can usually be found by diffraction methods. For molecules containing high symmetry, it is often useful to define a coordinate system based on molecule symmetry elements called the *molecular frame*. For molecules of low symmetry, coordinate systems can be defined based on the local symmetry of a particular nuclear site and these will be called *local frames*. Finally, there is an important coordinate system known as the *principal axis* system which is unique to each tensor. The principal axis system is discussed below.

The relationships between all of these reference frames, except for that between the sample frame and laboratory frame, are determined by the crystal and molecular structure, and therefore they are not under experimental control. It is clear from equation (11) that once the tensor is known in one of these reference frames, it can be expressed in any of the other frames provided the unitary matrix $\mathbf{R}$ is available.

For any symmetric second rank tensor such as the chemical shift tensor δ , there exists a unitary matrix $\mathbf{S}$ that transforms δ into a coordinate system in which it is diagonal

$$\mathbf{S} \delta \mathbf{S}^T = \mathbf{\Lambda} \quad (12)$$

where $\mathbf{\Lambda}$ is a diagonal matrix with elements λ_1 , λ_2 , and λ_3 . This special coordinate system is called the principal axis system and the diagonal tensor elements are called the principal values. Multiplying both sides of equation (12) by $\mathbf{S}^{-1} = \mathbf{S}^T$ yields

$$\delta \mathbf{S}^T = \mathbf{S}^T \mathbf{\Lambda} \quad (13)$$

Equation (13) is readily recognized as an algebraic eigenvalue equation and the eigenvalues (principal values) and eigenvectors (principal axes) can be found by solving the secular equation

$$|\delta - \Lambda \mathbf{I}| = \begin{vmatrix} \delta_{xx} - \lambda_1 & \delta_{xy} & \delta_{zx} \\ \delta_{xy} & \delta_{yy} - \lambda_2 & \delta_{yz} \\ \delta_{zx} & \delta_{yz} & \delta_{zz} - \lambda_3 \end{vmatrix} = 0 \quad (14)$$

A convention for labeling the principal values is generally followed in which they are designated δ_{11} , δ_{22} , and δ_{33} in order of decreasing chemical shift. An alternative to the Cartesian representation of a chemical shift tensor is its representation as three principal values and the three Euler angles that orient the principal axis system with respect to one of the coordinate systems defined above. Other useful representations of the chemical shift tensor are described elsewhere.¹⁰

Recalling equation (8), the chemical shift F observed when the magnetic field is oriented with direction cosines $\cos \gamma_x$, $\cos \gamma_y$, and $\cos \gamma_z$ relative to the sample frame axes can be explicitly written as the quadratic form

$$\begin{aligned} F &= [\cos(\gamma_x) \cos(\gamma_y) \cos(\gamma_z)] \begin{bmatrix} \delta_{xx} & \delta_{xy} & \delta_{zx} \\ \delta_{xy} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{yz} & \delta_{zz} \end{bmatrix} \begin{bmatrix} \cos(\gamma_x) \\ \cos(\gamma_y) \\ \cos(\gamma_z) \end{bmatrix} \\ &= \cos^2(\gamma_x) \delta_{xx} + \cos^2(\gamma_y) \delta_{yy} + \cos^2(\gamma_z) \delta_{zz} \\ &\quad + 2 \cos(\gamma_x) \cos(\gamma_y) \delta_{xy} + 2 \cos(\gamma_y) \cos(\gamma_z) \delta_{yz} \\ &\quad + 2 \cos(\gamma_z) \cos(\gamma_x) \delta_{zx} \end{aligned} \quad (15)$$

It is seen from equation (15) that if the chemical shift tensor δ is known in the sample frame, the chemical shift can be calculated for any orientation of $\mathbf{B}_0$. Alternatively, if the chemical shift F is known for six suitably chosen directions of $\mathbf{B}_0$, the elements of δ can be obtained by solving a system of linear equations.

Equation (15) takes on a particularly simple form when expressed in the principal axis system

$$F = \cos^2(\gamma_x) \delta_{11} + \cos^2(\gamma_y) \delta_{22} + \cos^2(\gamma_z) \delta_{33} \quad (16)$$

Provided that the reference frequency is chosen such that the three principal values δ_{11} , δ_{22} , and δ_{33} are positive, a connection can be made between equation (16) and the equation of an ellipsoid with semiaxes a , b , and c

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1 \quad (17)$$

The direction cosines of a radius vector $\mathbf{r}$ taken from the origin to a point on the surface of the ellipsoid are given by $\cos^2(\gamma_x) = x^2/r^2$, $\cos^2(\gamma_y) = y^2/r^2$, and $\cos^2(\gamma_z) = z^2/r^2$. Substituting these into equation (17) yields

$$\frac{r^2 \cos^2(\gamma_x)}{a^2} + \frac{r^2 \cos^2(\gamma_y)}{b^2} + \frac{r^2 \cos^2(\gamma_z)}{c^2} = 1 \quad (18)$$

Finally, by making the identities $a^2 = 1/\delta_{11}$, $b^2 = 1/\delta_{22}$, and $c^2 = 1/\delta_{33}$, equation (18) can be rearranged to give

$$\cos^2(\gamma_x) \delta_{11} + \cos^2(\gamma_y) \delta_{22} + \cos^2(\gamma_z) \delta_{33} = \frac{1}{r^2} \quad (19)$$

Figure 2 The chemical shift tensor representation ellipsoid

The surface described by equation (19) is called the representation ellipsoid¹¹ of the chemical shift tensor and is illustrated in Figure 2.

The semiaxes of the ellipsoid are given by $1/\sqrt{\delta_{11}}$, $1/\sqrt{\delta_{22}}$, and $1/\sqrt{\delta_{33}}$. Comparing equation (16) and (19), it is seen that when $\mathbf{B}_0$ is oriented along $\mathbf{r}$, the length of the radius vector is given by $r = 1/\sqrt{F}$.

The representation ellipsoid thus allows a geometrical interpretation of the chemical shift tensor, and the *mmm* (D_{2h}) symmetry of this object reflects the symmetry of the chemical shift interaction.

In order to understand the effect of crystallographic symmetry on the chemical shift, it is necessary to define some terminology. Nuclear sites related by the rotation or reflection symmetry operations of the space group of the crystal are called *crystallographically equivalent* sites. Those sites that are related by inversion or translation are called *magnetically equivalent* sites. This definition of magnetic equivalence is in contrast to that used in solution NMR where sites related by any symmetry element of the molecule are magnetically equivalent due to the rapid isotropic tumbling of the molecule. As the operations of either inversion or translation do not change the orientation of the representation ellipsoid, a set of magnetically equivalent sites gives rise to a single peak in the spectrum. On the other hand, the representation ellipsoids of crystallographically equivalent sites are oriented differently in the absence of accidental coincidence of the symmetry elements of the representation ellipsoid with those of the space group. Therefore, multiple peaks occur in the spectrum of a single crystal sample when the magnetic field is in a general orientation with respect to a lattice of crystallographically equivalent sites. Two tensors are said to be *congruent* if they are each associated with nuclear sites which are crystallographically equivalent. Congruent tensors have identical principal values, but differ in the orientations of their respective principal axes.

3 THE SINGLE AXIS ROTATION METHOD

In the case of a crystal containing only one set of magnetically equivalent nuclei, the measurement technique is straightforward since the spectrum of such a crystal contains a single peak in any orientation of the field. Six 1D spectra can be obtained with the magnetic field oriented along six different directions. The chemical shift derived from each spectrum, along with the corresponding direction cosines describing

the orientation of the magnetic field, is then substituted into equation (15) to obtain a set of six equations from which the tensor elements are extracted.

The spectrum of a sample containing multiple sets of magnetically equivalent nuclei has a corresponding multiplicity of peaks. In this case the six 1D spectra described above would be useless, since there would be no way to determine which peak in each of the spectra was from a particular set of magnetically equivalent nuclei. One solution to this problem is to acquire many 1D spectra which differ by small angle rotations of the crystal so that the paths of the lines can be traced from one spectrum to the next to form a *rotation pattern*.

Consider a rotation of the crystal about an axis that makes an angle β with the magnetic field $\mathbf{B}_0$. The arbitrary sample frame can be oriented such that the x axis is parallel to the rotation axis and the magnetic field $\mathbf{B}_0$ lies initially in the xy plane. If the crystal is rotated through an angle α , the direction cosines of the field with respect to the sample frame are given by

$$\cos(\gamma_x) = \cos(\beta) \quad (20)$$

$$\cos(\gamma_y) = \sin(\beta) \cos(\alpha) \quad (21)$$

$$\cos(\gamma_z) = \sin(\beta) \sin(\alpha) \quad (22)$$

It can easily be shown by substituting equations (20)–(22) into equation (15) that the chemical shift F is given by

$$F = A + B \cos(\alpha) + C \sin(\alpha) + D \cos(2\alpha) + E \sin(2\alpha) \quad (23)$$

where

$$A = \frac{1}{2} \sin^2(\beta) (\delta_{yy} + \delta_{zz}) + \cos^2(\beta) \delta_{xx} \quad (24a)$$

$$B = 2 \sin(\beta) \cos(\beta) \delta_{xy} \quad (24b)$$

$$C = 2 \sin(\beta) \cos(\beta) \delta_{zx} \quad (24c)$$

$$D = \frac{1}{2} \sin^2(\beta) (\delta_{yy} - \delta_{zz}) \quad (24d)$$

$$E = \sin^2(\beta) \delta_{yz} \quad (24e)$$

From equation (23) it is seen that if the chemical shift is observed at five different angles α , for a given angle β , the coefficients A , B , C , D , and E can be extracted. However, these five coefficients are insufficient to determine fully the six tensor elements and it is apparent that the complete chemical shift tensor cannot be measured from a single rotation pattern.

The most frequently used measurement technique is to obtain three patterns by rotating the crystal about a single axis perpendicular to $\mathbf{B}_0$ in the laboratory frame as depicted in Figure 3.

Figure 3 Schematic representation of a simple experimental set-up for obtaining single axis rotation patterns

The three rotation patterns are obtained first with the x , then the y , and finally the z sample frame axis along the rotation direction. The rotation pattern about the x axis is easily obtained from equations (23) and (24) by setting the angle β equal to $\pi/2$

$$F(\alpha_x) = \frac{1}{2}(\delta_{yy} + \delta_{zz}) + \frac{1}{2}(\delta_{yy} - \delta_{zz}) \cos(2\alpha_x) + \delta_{yz} \sin(2\alpha_x) \quad (25)$$

The other two rotation patterns can be found by cyclic permutation of the sample axis labels x , y , and z

$$F(\alpha_y) = \frac{1}{2}(\delta_{zz} + \delta_{xx}) + \frac{1}{2}(\delta_{zz} - \delta_{xx}) \cos(2\alpha_y) + \delta_{zx} \sin(2\alpha_y) \quad (26)$$

$$F(\alpha_z) = \frac{1}{2}(\delta_{xx} + \delta_{yy}) + \frac{1}{2}(\delta_{xx} - \delta_{yy}) \cos(2\alpha_z) + \delta_{xy} \sin(2\alpha_z) \quad (27)$$

Although each rotation pattern is fully determined by measuring the chemical shift at only three different angles, the usual practice is to obtain spectra at many angles by stepping the goniometer from 0° to 180° , and to extract the tensor elements using least-squares methods. This allows a more accurate determination of the tensor and is a necessity if the spectrum of the crystal contains many peaks, since the path of a single peak can be traced only when the crystal is rotated in small angular increments. In order to obtain all six elements of the chemical shift tensor for a particular set of magnetically equivalent nuclei, the path of the corresponding peak must not only be traced within each rotation but must also be traced between rotations. This is accomplished by matching up the rotation patterns at the orientations where they intersect. Figure 4 shows three rotation patterns from which the ^{13}C chemical shift tensors of naphthalene can be obtained.

The rotation method has been successfully applied to many medium-sized molecules;¹² however, it fails when the peaks in the spectra become numerous and crowded since it becomes impossible to trace the paths of individual peaks through the three rotation patterns. Another drawback of the rotation method is the necessity of accurately mounting the crystal three times along the three orthogonal sample axes, but this problem has been overcome using a two-axis goniometer and a unique rf coil as demonstrated by Hauser et al.¹³

Figure 4 Rotation patterns through 180° about the x , y , and z sample axis sufficient to measure the 10 chemical shift tensors in single crystal naphthalene

4 SINGLE AXIS 2D CHEMICAL SHIFT TENSOR CORRELATION SPECTROSCOPY

The necessity of taking small angular increments in the rotation patterns can be eliminated using a 2D correlation method introduced by Carter et al.¹⁴ This technique obtains 2D spectra in which a peak from a single set of magnetically equivalent nuclei is located by its resonant frequencies at two different orientations of the single crystal. Such spectra are obtained with the modified 2D chemical exchange¹⁵ pulse sequence shown in Figure 5.

The preparation period of this sequence is identical to the usual cross-polarization experiment. During the evolution period, the spins precess at frequencies determined by their chemical shifts at the initial crystal orientation. The evolved magnetization is then stored along the z axis with the pulse labeled b and the crystal is reoriented during the mixing period. At the end of the mixing period, the stored magnetization is rotated back to the transverse plane with the pulse labeled a , and during the detection period the spins precess at frequencies determined by their chemical shifts at the final crystal orientation. An example of a 2D chemical shift tensor correlation spectrum is shown in Figure 6 where all 24 peaks in

Figure 5 Modified chemical exchange sequence for 2D chemical shift tensor correlation spectroscopy. See text for details. (Reproduced by permission of Academic Press from M. H. Sherwood, D. W. Alderman, and D. M. Grant, *J. Magn. Reson.*, 1989, **84**, 466)

Figure 6 Two-dimensional absorption mode spectrum obtained from sucrose corresponding to a reorientation of B_0 by 90° in the sample frame. The plotted spectral width is $5 \text{ kHz} \times 5 \text{ kHz}$ (approximately $100 \text{ ppm} \times 100 \text{ ppm}$). The spectrum diagonal runs from upper left (high frequency) to lower right (low frequency). (Adapted by permission of Academic Press from M. H. Sherwood, D. W. Alderman, and D. M. Grant, *J. Magn. Reson.*, 1989, **84**, 466)

single crystal sucrose are resolved despite the severe crowding that exists in the corresponding 1D spectra.

It has been shown that the information present in one rotation pattern can be obtained from four 2D spectra taken while stepping the sample from 0° to 45° , 45° to 90° , 90° to 135° , and 135° to 180° (equivalent to 0°).¹⁶ The redundancy in this information permits a powerful square construction which resolves the uncertainties due to peak overlap within each rotation. However, this single axis 2D technique does

not address the problem of joining the three rotation patterns together when there are many overlapping lines in the spectra at the orientations where the patterns intersect. Thus the application of the single axis 2D method is limited to samples where the connections can be made by conventional means. As in the traditional 1D method, it is necessary to mount the sample accurately three times for the single axis 2D measurements.

5 MULTIPLE AXIS 2D CHEMICAL SHIFT TENSOR CORRELATION SPECTROSCOPY

The full power of the 2D technique can be realized by gathering data in such a way that all correlations between required crystal orientations are obtained with a single mounting of the crystal. This is accomplished with a multiple axis sample orienting mechanism which complements the 2D method to form an exceedingly powerful technique for measuring chemical shift tensors in complex single crystals.¹⁷

As mentioned above, the six independent elements of a chemical shift tensor, in principle, can be determined by measuring the chemical shift with the magnetic field oriented along six suitably chosen directions. Table 1 gives the orientations of six such directions in the sample frame.

Table 1 Six Magnetic Field Directions in the Sample Frame That can be Used to Measure a Chemical Shift Tensor

Magnetic field direction	$\cos(\gamma_X)$	$\cos(\gamma_Y)$	$\cos(\gamma_Z)$	Observed shift
X	1	0	0	F_X
XY	$1/\sqrt{2}$	$1/\sqrt{2}$	0	F_{XY}
Y	0	1	0	F_Y
YZ	0	$1/\sqrt{2}$	$1/\sqrt{2}$	F_{YZ}
Z	0	0	1	F_Z
ZX	$1/\sqrt{2}$	0	$1/\sqrt{2}$	F_{ZX}

These directions lie on the surface of a trigonal pyramid and will be referred to here as the pyramidal directions. The observed chemical shifts F_X , F_{XY} , F_Y , F_{YZ} , F_Z , and F_{ZX} are easily calculated from equation (15), yielding the relationships

$$F_X = \delta_{xx} \quad (28a)$$

$$F_{XY} = \delta_{xy} + \delta_{xx}/2 + \delta_{yy}/2 \quad (28b)$$

$$F_Y = \delta_{yy} \quad (28c)$$

$$F_{YZ} = \delta_{yz} + \delta_{yy}/2 + \delta_{zz}/2 \quad (28d)$$

$$F_Z = \delta_{zz} \quad (28e)$$

$$F_{ZX} = \delta_{zx} + \delta_{zz}/2 + \delta_{xx}/2 \quad (28f)$$

which trivially invert to

$$\delta_{xx} = F_X \quad (29a)$$

$$\delta_{xy} = F_{XY} - F_X/2 - F_Y/2 \quad (29b)$$

$$\delta_{yy} = F_Y \quad (29c)$$

$$\delta_{yz} = F_{YZ} - F_Y/2 - F_Z/2 \quad (29d)$$

$$\delta_{zz} = F_Z \quad (29e)$$

$$\delta_{zx} = F_{ZX} - F_Z/2 - F_X/2 \quad (29f)$$

By obtaining the six 2D spectra corresponding to reorientation between the X - XY , XY - Y , Y - YZ , YZ - Z , Z - ZX , and ZX - X direction pairs, the correlation data are sufficient to determine the complete chemical shift tensors for all of the sets of magnetically equivalent nuclei in the sample. Starting first with the X - XY 2D spectrum, the chemical shifts of the X and XY directions are measured and correlated. Then the observed chemical shifts in the XY direction from the X - XY spectrum are matched with those from the XY - Y spectrum to advance the correlation of the chemical shift to the Y direction, and so forth through YZ , Z , ZX , and back to X . After completion of the full cycle of reorientations, the chemical shift is known for each set of magnetically equivalent nuclei at all six orientations and the tensor elements can be calculated from equations (29a)–(29f). The correlation of chemical shifts around the full cycle forms the closed path depicted in Figure 7(a).

It may be noted that the sense of the reorientation is unimportant. The same frequency information is obtained by reorienting from the X to the XY direction as is obtained by reorienting from XY to X . The only consequence is to interchange the F_1 and F_2 axes of the spectrum.

A powerful criterion, analogous to the square construction described for the single axis 2D approach, allows the correlation of peaks which have identical frequencies at one or more of the six magnetic field directions. It employs reorientations between other pairs of the six measurement directions. The full matrix of 36 possible 2D correlation spectra is shown in Figure 7(b). The 2D spectra that lie along the diagonal of this matrix correspond to trivial correlations between two identical orientations, and are thus of no experimental value. The spectra related by the transpose of this matrix differ only by the sense of the reorientation, and contain the same correlation information. Therefore, only 15 of the 36 possible spectra are necessary to obtain all of the available correlation and frequency information. The spectra matrix construction allows the chemical shifts of a single set of magnetically equivalent nuclei to be traced through all 15 possible 2D correlation spectra simply by connecting the peaks with horizontal and vertical lines as shown in Figure 7(b).

A mechanism which accomplishes the 15 flips has been described in detail elsewhere.¹⁷ Briefly, it consists of an armature into which a glass tube containing the sample is

Figure 7 Matrix of 2D spectra. (a) Six 2D spectra corresponding to $XY-X$, $XY-Y$, $YZ-Y$, $YZ-Z$, $ZX-Z$, and $ZX-X$ reorientations. The relationship of the peaks in these spectra is shown for a single set of magnetically equivalent nuclei by the vertical and horizontal connecting lines. Dotted lines indicate the diagonals in the spectra. (b) All 36 possible 2D spectra. The relationship of the peaks in the spectra is shown for a single set of magnetically equivalent nuclei by the vertical and horizontal connecting lines. The six unshaded spectra with dotted diagonals correspond to those of Figure 7(a). The six darkly shaded spectra with solid diagonals are the trivial autocorrelation spectra with the peaks on the diagonals (Reproduced by permission of Academic Press from M. H. Sherwood, D. W. Alderman, and D. M. Grant, *J. Magn. Reson.*, 1989, **84**, 466)

mounted. The armature contains seven accurately drilled holes which define seven rotation axes in the sample frame. A stationary plate attached to the NMR probe contains five axle bearing holes which define five rotation axes in the laboratory frame. The mechanism is assembled by inserting an axle through one of the bearings in the stationary plate

and into one of the holes in the armature. By selecting the appropriate combination of bearing and armature hole, each of the 15 possible flips can be performed. The angle of rotation is limited by a precise system of stops. One advantage of this mechanism is that the axis of the tube containing the sample changes by only 19.5° over all assemblies of the mechanism, so that a reasonably good filling factor can be achieved in the rf solenoid.

Although the pyramidal set of directions was used in the original demonstration of multiple axis 2D chemical shift tensor correlation spectroscopy, it should be realized that any set of six directions would suffice if when substituted into equation (15) they yield a system of linearly independent equations for the six chemical shifts. This restriction eliminates any set of directions that completely lie either in a plane or on the surface of a cone.

An important question that arises is how sensitive is the determination of a tensor given a particular set of measurement directions. To address this question, a variance-like figure of merit was developed¹⁸ which quantifies the sensitivity of a given set of measurement directions. This figure of merit was evaluated for a variety of sets of measurement directions including the pyramidal set and the orthogonal rotation set. The most sensitive set of directions was found to be the six apolar directions defined by the vertices of an icosahedron. For this geometry, the figure of merit represents a significant decrease by a factor of 1.0/1.8 from that of the pyramidal directions. Therefore, it is worth considering the icosahedral direction set when designing future mechanisms. It should be noted that there is no further increase in sensitivity upon including more measurement directions than the six icosahedral directions. Another interesting result of this analysis is that the figure of merit for the orthogonal rotations set is only 1.2 times greater than that for the icosahedral directions set. This indicates that the sensitivity of the tensor measurements made using the traditional rotation method is nearly optimal.

The high symmetry of the icosahedron makes possible a very simple mechanism which rotates the crystal about a single laboratory axis inclined at an angle of 64.4° from the field. As can be seen in Figure 8, it will still be necessary to employ three rotation axes in the sample frame as specified by the three vertices labeled a, b, and c. Unfortunately the sample tube axis will reorient by 68.3° in this new mechanism, and a sacrifice in filling factor may be necessary when implementing this geometry.

Figure 8 Icosahedra showing the vertex directions which can be aligned along the magnetic field by rotating around the a vertex (a), the b vertex (b), and the c vertex (c) (Reproduced by permission of Academic Press from D. W. Alderman, M. H. Sherwood, and D. M. Grant, *J. Magn. Reson.*, 1990, **86**, 60)

6 ASSIGNMENT TECHNIQUES

Before chemical shift tensors can be rationalized in terms of molecular structure, they must first be assigned to their respective nuclei in the unit cell. This can be a challenging step in the interpretation of the results, since the number of possible assignment permutations increases rapidly for larger molecules. The problem is compounded by the fact that most organic crystals contain two or more magnetically nonequivalent molecules in the unit cell. In order fully to exploit the power of the techniques described above, systematic methods of assignment have been developed based on local symmetry and dipolar spectroscopy. These methods have been described in detail in the literature and therefore will only be described qualitatively here.

Nearly all of the chemical shift tensor assignments made to date are based on the assumption that the symmetry elements of the representation ellipsoid should closely coincide with the actual or approximate local symmetry of its assigned nuclear site. For example, it is well established that the δ_{33} principal values of the ^{13}C chemical shift tensors orient perpendicular to the molecular plane in polycyclic aromatic hydrocarbons.¹⁹ This fact is widely used to assign tensors to a particular molecule when there is more than one molecule in the unit cell. In more complicated molecules lacking any molecular symmetry, the approximate local symmetry established by the directly bonded atoms can be used to make assignments. For small molecules this procedure consists of manually comparing principal axis directions of the measured tensors with the approximate local symmetry elements determined from diffraction data until a reasonable match is found. As the number of measured tensors increases, it becomes more difficult to make all possible comparisons and their qualitative nature makes it difficult to distinguish between closely related assignments. In order to quantify such comparisons, the concept of a distance between two tensors was developed.¹⁰ This distance concept has been combined with linear modeling in order to make possible an automated assignment technique which can explore all possible assignments of a reasonably large set of measured tensors to a corresponding set of chemically similar but magnetically nonequivalent nuclear sites.^{10,20}

The orientational dependence of dipolar interactions has also been exploited in order to assign chemical shift tensors to specific nuclei in single crystal samples. Assignments made in this way are quite reliable since dipolar couplings can be calculated with a high degree of accuracy from the positions of the nuclei alone without resorting to molecular electronic theory. In many organic molecular crystals, the positions of all of the carbon and hydrogen nuclei in the unit cell are known from neutron diffraction studies and thus ^{13}C – ^1H separated local field experiments^{21,22} can be used in solving the assignment problem.

A simple extension of 2D chemical shift tensor correlation spectroscopy yields a 3D technique which allows detection of ^{13}C – ^1H dipolar couplings for each of the magnetically nonequivalent sets of carbons in the sample.²⁰ The response of each spin is separated according to its chemical shifts at two different magnetic field orientations and a dipolar spectrum is displayed in the third dimension. This is accomplished by inserting a dipolar evolution period between the end of the mixing time and the beginning of the detection period of the previously described 2D experiment.

1 INTRODUCTION

The advances in NMR over the last three decades have resulted in an increasingly important role that this technique has played in studies of various types of carbonaceous materials. Among these materials are fossil fuels which, due to their impact as a main world energy source, are of primary concern in scientific and engineering research. Of great interest are naturally occurring raw materials, such as coal, crude oil, and oil shales, as well as products of fossil fuel processing. The latter include 'coke', a term used to describe a solid by-product of the petroleum refining process, or a hard, often porous residue left after the destructive distillation (pyrolysis) or liquefaction of coal.

Fossil fuels are known to be enormously heterogeneous and complex materials and no single approach can provide adequate understanding of their structure and best way of utilization. Although the classical chemical methods and some modern analytical techniques (e.g. mass spectroscopy, liquid and gas chromatography, thermogravimetry) have proved useful in characterizing parent materials as well as liquid and gaseous products of coals and petroleum processing, determination of the chemical and physical structure of solid fossil fuels and solid products of fuels processing has not been possible by employing these methods. This need has stimulated application of other spectroscopic techniques including X-ray spectroscopies (X-ray atomic fluorescence and X-ray photoelectron spectroscopy), infrared spectroscopy, optical spectroscopies (laser spark spectroscopy, Raman spectroscopy), ESR spectroscopy, and NMR spectroscopy, which soon came to the forefront of this research. Earlier NMR studies utilized primarily relaxation studies, quantitative analysis of ^1H in solids using wideline NMR, and provided quantitative and structural analysis of fossil fuel derived liquids (mainly from coal and petroleum) via liquid state NMR. Since the implementation of high-resolution methods of ^1H decoupling, magic angle spinning and CRAMPS, and the methods of enhancing polarization of rare nuclear spins (cross polarization and dynamic nuclear polarization) it became possible to acquire high-resolution spectra of ^1H and ^{13}C in a short measuring time.¹

In spite of different origins, petroleum and coal derived cokes consist primarily of carbon (typically ca. 90% by weight)

and hydrogen (below 5%). While smaller concentrations of oxygen, sulfur, nitrogen and various metals (vanadium, nickel, iron) are also present in cokes, it is not surprising that NMR spectroscopy utilizes ^1H and ^{13}C nuclei to probe these materials. Below, an overview is given of the fundamental aspects of solid state NMR of ^1H and ^{13}C as applied to the studies of carbonaceous solids. The topics include relaxation studies, quantitation, high-resolution methods in ^{13}C and ^1H NMR, lineshape analysis, and the relationship between NMR derived data and the chemical structure. Although the utilization of solid state NMR techniques will be shown largely for petroleum derived cokes, most of the approaches described here are also pertinent to fossil fuels, semi-cokes, coal tar pitches, petroleum pitches and other 'bottom-of-the-barrel residues' (see also *Coal Structure from Solid State NMR and Fossil Fuels*), as well as for characterization of carbonaceous residues (cokes) from catalyst-controlled reactions.

2 RELAXATION PARAMETERS OF HYDROGEN AND CARBON IN COKES

Measurements of nuclear spin relaxation in solid fossil fuels have been performed in order to provide gross information about local environments and molecular motions, long before modern high-resolution solid state NMR techniques were introduced as an analytical tool. Three relaxation times were commonly measured: (a) T_1 , the longitudinal relaxation time characterizing attainment of equilibrium of spin magnetization along a static magnetic field, and generally associated with dipolar fields fluctuating at the Larmor frequency, generated by motion of other magnetically active nuclei and/or unpaired electron spins associated with free radicals; (b) $T_{1\rho}$, the longitudinal relaxation time in the rotating frame characterizing similar motions in the tens of kilohertz frequency range; and (c) T_2 , the transverse relaxation time characterizing static spin interactions in solids.

Most of the spin-lattice relaxation studies reported for cokes employed ^1H NMR and showed that T_1^{H} and $T_{1\rho}^{\text{H}}$ relaxation processes (typical values in the 50–200 ms and 0.3–5 ms range, respectively) depend upon interactions between protons and unpaired electrons (via spin diffusion), while dipolar interactions between protons have a lesser significance. To limit the number of parameters, only a biexponential function is usually used to fit the experimental data although no physical model that justifies such procedure has yet been established. Also, due to the presence of different relaxation mechanisms, and different types of paramagnetic species, a distribution of relaxation parameters is very likely. In such cases the relaxation parameters are the result of a complicated interplay between competing relaxation mechanisms, and spin diffusion may not be effective to identify structural inhomogeneities, even if they existed in cokes. For example, the detailed study of 15 petroleum cokes, produced from pure and mixed residues of various origins, showed that the T_1^{H} and $T_{1\rho}^{\text{H}}$ relaxation parameters (including relative fractions of magnetization exhibiting fast and slow relaxation) could not be directly correlated with different structural parameters of cokes as determined by high-resolution methods.² In particular, these results did not reveal structural inhomogeneities in cokes in which

aliphatic and aromatic structures dominate. In spite of difficulties with the interpretation of spin lattice processes in cokes, the accurate analysis of T_1^H and $T_{1\rho}^H$ is often required to characterize quantitatively the cokes via ^{13}C CP MAS experiments.

The proton T_2 relaxation time (or the NMR linewidth), determined under a single pulse excitation, reflects the strength of static ^1H – ^1H dipolar interactions in cokes, and in the absence of molecular motion is a measure of the average internuclear distance in a sample. Unlike coals, which generally exhibit at least two exponential decays, the pyrolyzed cokes show typically a Gaussian decay of transverse magnetization with a single value of T_2 of roughly $20\ \mu\text{s}$, indicating homogeneously rigid character of the coke structure, where only hindered motions of functional groups (e.g. CH_3) take place.² When molecular motion characterized by correlation time $\tau_c < 10^{-5}\text{ s}$ is present, e.g. in coals with mobile molecular fragments, solvent swollen coals, pitches above their softening point or during pyrolysis, the increased values of T_2 are a measure of molecular mobility. The measurements of T_2 versus temperature allowed the study, for example, of the glass transition temperature in materials resulting from pyrolysis of petroleum pitches and coal extracts through the mesophase stage to a coke.³

3 QUANTITATION OF HYDROGEN AND CARBON

One of the main reasons NMR has become a powerful analytical tool is because for spin- $\frac{1}{2}$ nuclei, such as are ^1H and ^{13}C , the NMR signal may generally be used for quantitative analysis. Using NMR for hydrogen (or carbon) spin counting in cokes implies that: (1) all spins are observed by NMR, (2) the initial (near $t = 0$) time dependence of the FID is known and can be compared with that of a standard, and (3) the physical meaning of all components of the FID is well understood. In single pulse experiments the first few microseconds of the FID are always obscured by the probe ringdown and receiver deadtime, which may result in considerable signal loss in samples with short T_2 . This short time behavior of the NMR signal can be determined, and the lost intensity recovered, by using a solid echo excitation sequence, or by applying linear prediction techniques directly to the FID.²

Hydrogen is the most sensitive nucleus commonly detected by NMR, but it is also one of the least sensitive when analyzed by chemical methods. In general, NMR offers quick and most reliable measurements of hydrogen concentration in fossil fuel materials, which compare favorably with the results of combustion analysis, Karl–Fisher titration and other techniques. The main possible source of systematic loss of the NMR signal (typically below 10%) is the broadening of the NMR line from dipolar interactions with unpaired electrons present in organic free radicals in cokes. As already mentioned, the analysis of the FID also provides information about molecular mobility.

The quantitative analysis of carbon by single pulse NMR is time consuming due to long ^{13}C relaxation times T_1^C and is considered less accurate than chemical analyses. It is mainly used to address the potential quantitation problems in the CP MAS spectra.

4 NMR LINESHAPES IN COKES

The dominant line broadening interactions that affect the NMR lineshapes are chemical shift anisotropy and ^1H – ^1H and/or ^1H – ^{13}C dipolar couplings. However, even if these interactions are eliminated, or reduced, by the high-resolution techniques, the observation of sharp resonances in ^1H and ^{13}C NMR is often precluded by the heterogeneous chemical nature of cokes. The results of high-resolution ^1H and ^{13}C NMR when combined with spin counting, elemental analysis, and other analytical methods, can be used to infer several structural parameters and the ‘average’ model of a coke.

4.1 ^1H CRAMPS NMR

With values of transverse relaxation times T_2 around $20\ \mu\text{s}$, proton linewidths in cokes are ca. 30 kHz, corresponding to 100 ppm at a resonance frequency of 300 MHz. This line broadening results from high abundance and large magnetic moment of ^1H spins, and exceeds the range of proton chemical shifts in hydrocarbons, which is about 15 ppm. Consequently, no information concerning chemical environment of hydrogen can be derived from the NMR spectrum, unless the ^1H – ^1H dipolar interactions are overcome by a suitable NMR technique. However a combination of MAS and homonuclear dipolar decoupling via a multiple pulse sequence (WAHUHA, MREV or BR-24) allows the achievement of quantitative ^1H NMR spectra with linewidths of less than 0.3 ppm in favorable cases [Figure 1(a)]. This technique is referred to as CRAMPS (combined rotation and multiple pulse spectroscopy) (see **CRAMPS**).⁴

In general, CRAMPS spectra of cokes are less resolved than the spectra of pure crystalline hydrocarbons and some coals; nevertheless, two absorption bands can usually be distinguished, centered at ca. 7 ppm and ca. 2 ppm, and associated with aromatic CH protons, and protons attached to sp^3 carbon atoms, respectively (Figure 1).^{2,5} The linewidths corresponding to the two maxima are typically 3–5 ppm [full width at half maximum height (FWHM)], with the inhomogeneous broadening mainly attributed to distribution of chemical shifts. The use of the MREV-8 sequence seems satisfactory for CRAMPS spectroscopy of fossil fuels, as the application of more sophisticated pulse sequences like BR-24 does not lead to increased resolution in these materials. Due to substantial overlap of the aromatic and aliphatic peaks, the spectra are deconvoluted for quantitative analysis by using a superposition of Gaussian lines. The usefulness of the CRAMPS technique becomes apparent when differences in the spectra are viewed as a function of coking conditions, e.g. time or temperature of pyrolysis.⁶

4.2 ^{13}C NMR Techniques: CP MAS and Bloch Decay

^{13}C NMR spectra of cokes, coals and coal-derived products can be measured using conventional single pulse excitation (Bloch decay experiment), or by ^1H – ^{13}C cross polarization, which, combined with high-power ^1H decoupling and MAS, yield spectra with well resolved aromatic and aliphatic carbon bands (Figure 2). Typically, the low-frequency (aliphatic) part of the spectrum consists of a peak located between 10 and

Figure 1 ^1H CRAMPS spectra of (a) citric acid, 187 MHz; (b) Pittsburgh No. 8 Argonne Premium Coal, 300 MHz; and (c) petroleum coke produced at Mobil from heavy crude oil, 300 MHz. [Spectrum (a) reproduced by permission of Academic Press from G. E. Maciel, C.E. Bronnimann, and B.L. Hawkins, in 'Advances in Magnetic Resonance: The Waugh Symposium', ed. W.S. Warren, 1990, Vol. 14, p. 125. Spectrum (c) reproduced by permission of Pergamon Press from M. Pruski, D. Michel, and B. C. Gerstein, *Carbon*, 1994, **32**, 31]

50 ppm with features that can be assigned to methyl and methylene carbons. The aromatic peak, centered at ca. 130 ppm, is associated mainly with C–H perimeter and nonprotonated aromatic carbons. Although ^1H decoupling and MAS substantially reduce the large broadening due to ^1H – ^{13}C dipolar interaction (ca. 20 kHz) and chemical shift anisotropy (ca. 200 ppm), the ^{13}C spectra of coals and cokes cannot match the liquid-like resolution achieved for many crystalline organic compounds (Figure 2). Again, NMR reflects the chemical complexity of these materials, because the resonances originating from a distribution of chemical environments are superimposed in the spectra.

A variety of sources can limit the accuracy of the intensities measured in these experiments which raised serious concern about the quantitative reliability of ^{13}C NMR methods in the analysis of carbonaceous solids.⁷ Several factors that define resolution and quantitative information are general for ^{13}C NMR spectroscopy, e.g. interference of molecular motions with MAS and ^1H decoupling, incomplete recovery of carbon magnetization in Bloch decay experiments due to very long

Figure 2 25 MHz ^{13}C CP MAS spectra of (a) sucrose, (b) German brown coal, and (c) petroleum coke produced from heavy crude oil ($t_{\text{CP}} = 1$ ms, spinning speed $\nu_r = 4.5$ kHz)

T_1^{C} relaxation times, and signal loss due to broadening from paramagnetic centers (cokes contain typically ca. 10^{19} unpaired electrons per gram).

Additional difficulties arise when cross polarization is used to enhance the carbon signal.^{7–10} The time evolution of carbon magnetization during the CP MAS experiment is a result of a complicated interplay between the spin–lattice relaxation processes in the rotating frame and the cross-polarization processes (described by relaxation time $T_{1\rho}^{\text{H}}$ and the time constant for cross-polarization process, T_{CH}), which, in turn, are further influenced by sample spinning and sample heterogeneity (see *Cross Polarization in Rotating Solids: Spin-1/2 Nuclei*). In the simplest case, the time dependence of the ^{13}C magnetization $M_{\text{c}}(t_{\text{CP}})$ during the cross polarization contact is given by:

$$M(t_{\text{CP}}) = M_0 \lambda^{-1} \left[1 - \exp \left(-\lambda \frac{t_{\text{CP}}}{T_{\text{CH}}} \right) \right] \times \exp \left(-\frac{t_{\text{CP}}}{T_{1\rho}^{\text{H}}} \right) \quad (1)$$

where M_0 is the carbon equilibrium magnetization, t_{CP} is the cross polarization contact time, and $\lambda = 1 - (T_{\text{CH}}/T_{1\rho}^{\text{H}})$.¹¹ For quantitative measurements it is required that the build-up of carbon magnetization, determined by T_{CH} , is completed before the loss of proton polarization occurs due to $T_{1\rho}^{\text{H}}$ relaxation (i.e. hydrogen having short $T_{1\rho}^{\text{H}}$ values are not contributing to cross polarization, leaving a substantial fraction of carbons ‘undetected’, unless $T_{\text{CH}} \ll T_{1\rho}^{\text{H}}$). In general, a wide distribution of T_{CH} times exists in cokes due to different ^{13}C – ^1H distances and internal motion. MAS introduces additional time dependencies to homo- and heteronuclear dipolar Hamiltonians and further complicates the polarization transfer. Since, as described earlier, the $T_{1\rho}^{\text{H}}$ relaxation processes are also complex in cokes, with substantial fractions of spins having $T_{1\rho}^{\text{H}}$ values of 500 μs or less,² the condition $T_{\text{CH}} \ll T_{1\rho}^{\text{H}}$ may not be satisfied for those ^{13}C nuclei that are far from the nearest proton, e.g. those that are deeply incorporated in polycondensed aromatic rings.

In spite of the unfavorable cross-polarization dynamics, CP MAS experiments are being successfully applied in the studies of fossil fuels. Most researchers have conceded that, when carefully performed, CP MAS experiments provide quite accurate ^{13}C lineshapes, which in most cases agree well with those obtained from Bloch decay experiments. This assertion seems particularly pertinent for cokes, which by nature are more homogeneous than coals, and a too low carbon spin count in the CP MAS spectra does not necessarily imply an incorrect analysis of carbon functionality. In addition, several CP MAS-based spectral editing techniques have been proposed and applied to carbonaceous solids. The dipolar dephasing experiment has been traditionally used for discriminating between different carbons based on the strength of their dipolar interactions with protons.¹² In coals and cokes, this technique allowed discrimination between aromatic tertiary and aromatic quaternary ring carbons, as well as between aliphatic quaternary and CH_3 carbon atoms and combined CH and CH_2 .^{12,13} The recently proposed CP MAS sequences that combine depolarization and polarization inversion allow the generation of subspectra representing each of four CH_n ($n = 0, 1, 2, 3$) subsystems (see *Spectral Editing Techniques: Hydrocarbon Solids*).¹⁴

The following experimental conditions and procedures are recommended for obtaining the most reliable CP MAS spectra of solid fossil fuels.^{7,9,10}

1. The longitudinal relaxation times $T_{1\text{H}}$ and $T_{1\rho}^{\text{H}}$ should be carefully measured using ^1H NMR.
2. Measuring of ^{13}C intensities with variable cross-polarization contact times in the 10 μs to 30 ms range, and fitting the data to equation (1) to obtain the total magnetization $M_{\text{c}}(0)$. Often two components of T_{CH} and $T_{1\rho}^{\text{H}}$ are necessary to produce a good fit.
3. The use of low MAS frequency (<5 kHz) is useful to avoid the interference of sample spinning with the cross-polarization process. Consequently, the measurements should be performed at low static magnetic fields (<2.5 T) to avoid the spinning sidebands in the spectra and the necessity of spinning sideband suppression. Since the dominant line broadening mechanisms in the CP MAS

spectra are heterogeneous, resolution is almost independent on the magnetic field strength.

4. Accurate adjustment of the Hartmann–Hahn match, especially when MAS frequencies of >5 kHz are used.

Finally, the last few years have seen the development of a variety of CP MAS based experiments designed in order to enable efficient cross polarization and evade some of the quantitative distortions in ^{13}C NMR spectra. These techniques include stop-and-go spinning (STAG),¹⁵ magic angle hopping¹⁶ (see *Magic Angle Turning and Hopping*) and amplitude-modulated cross polarization schemes (AMCP).¹⁷

While the CP MAS technique is applied in most studies, the Bloch decay experiment has recently become a feasible alternative. With the advent of large MAS rotors, spinning of several cubic centimeters of sample is now possible at 4 kHz, and a reasonable signal-to-noise (S/N) ratio can be achieved in ^{13}C MAS spectra of cokes within a few hours of measuring time, even if the recycle delay of several minutes is required between successive transients.¹⁸ The Bloch decay spectra represent >90% of carbon in many cokes, with the only loss of signal attributed to paramagnetic broadening, and the method is preferable for quantitative studies. As the MAS capabilities continue to improve, Bloch decay may become increasingly used in the future research, leaving CP MAS measurements for quick qualitative surveys, comparative studies, measurements of C–H interactions and spectral editing.

4.3 Other NMR Techniques

The rotating frame dynamic nuclear polarization cross polarization experiment (rf DNP-CP)¹⁹ is an alternative ^1H – ^{13}C polarization scheme which allows nuclear polarization to be enhanced by irradiating the free electrons in a sample. The DNP technique is particularly well suited for solid fossil fuels and substantial carbon signal enhancements have been reported for coals.¹⁹ The DNP experiment requires, however, a source of microwave power and some modifications of the NMR spectrometer (see *Dynamic Nuclear Polarization and High-Resolution NMR of Solids*).

Variable angle sample spinning (VASS) is another method which partly averages the chemical shift anisotropy while allowing measurements of CSA lineshapes and CSA tensor values (see *Variable Angle Sample Spinning*). The technique has proved useful in supplementing other types of NMR data to estimate the structure of polycondensed aromatic materials such as some coals and chars.⁹

Also, high temperature in situ NMR has recently embraced fossil fuels and related materials.²⁰ Several NMR studies were reported in which thermally induced changes in molecular dynamics and chemical shift information during pyrolytic decomposition and formation of solid carbonaceous residues, including coking processes, have been monitored at temperatures as high as 800 K. For these materials, which could be studied above their softening point (e.g. hard coal tar pitch and mesophase pitch prepared from decant oil), ^1H and ^{13}C NMR provided highly resolved signals (<1 ppm) that allowed for identification of various structural units.²¹

5 STRUCTURAL PARAMETERS OF COKES

The primary implication of solid state NMR studies of cokes is an enhanced understanding of their chemical

composition. Although the structural information obtained from solid state NMR studies is less detailed than that provided for the feedstocks using liquid state NMR techniques,²² the parameters measured by ¹H and ¹³C NMR can be used to estimate the 'average' models of these materials.^{2,8} The parameters include: hydrogen and carbon concentrations (from quantitative NMR analysis); hydrogen and carbon aromaticities, as obtained from high-resolution NMR of ¹H and ¹³C; fraction of aromatic carbon atoms with directly bonded protons (from ¹³C NMR with dipolar dephasing); the total H/C mole ratio; and the mole fractions H/C (aromatic) and H/C (aliphatic). Due to their heterogeneity, the validity of 'average' models to describe coals has been questioned by some researchers. However, it is often useful to describe these materials in terms of average properties, as the identification of all individual constituents is very difficult, if not impossible, to accomplish. Also, NMR and elemental analysis show that cokes are more chemically homogeneous, and have low concentrations of heteroatoms, which facilitates structural determination. Two examples of basic structural types present in cokes produced from heavy crude oils by delayed coking at ca. 700 K are shown in Figure 3.² These materials may be viewed as high molecular weight conglomerates of polycyclic aromatic, hydrogen deficient structures, formed by covalent bonds or methylene bridges. The structures shown in Figure 3 are typical of cokes, although carbon aromaticities close to 100% were observed for materials produced under more severe coking conditions. Similar structural parameters were also measured for coal liquefaction residues, coal tar pitches, and residual carbons (coke) from thermal decomposition of oil shales.²³ In the last study, a CP MAS technique was used to monitor the decrease of aliphatic carbon peak intensity and formation of polycondensed quaternary carbon at higher temperatures.

For a variety of fossil fuels, solid state NMR spectra can be combined with characterization of feedstocks by liquid state NMR, MRI and high temperature in situ NMR to provide unique identification of structural changes during the entire coking, pyrolysis or liquefaction processes. Such studies

allow monitoring of the loss of organic aliphatic matter, while cracking, polymerization and aromatization reactions progress during pyrolysis and the precursors of coke are formed. Following the progress of these reactions has notably improved the understanding of the chemistry of carbonization, and allowed optimization of the technology used in the coking process.

1 INTRODUCTION

Combined rotation and multiple pulse spectroscopy (CRAMPS)¹ is one means of using transient techniques in NMR to achieve liquid-like high-resolution NMR spectra of hydrogen and fluorine in solids. Herein will be described the basic ideas leading to the achievement of this resolution. The background required is that obtained by exposure to an undergraduate physical chemistry course, with a smattering of perturbation theory included. There will necessarily be some overlap between the description below, and other articles in this Encyclopedia. Cross references to pertinent subjects are given at the end of the article.

Of all the elements encountered by medical, biological, chemical, and physical scientists, hydrogen is perhaps the most common. The NMR-active nuclide, ^1H , is 99.98% abundant, and the magnetic moment is exceeded in magnitude only by the nonnaturally occurring tritium, ^3H . ^1H was the first nucleus for which NMR was reported.^{2,3} Because of the magnitude of its magnetic moment, and its natural abundance, hydrogen is the most easily detected nucleus commonly encountered in NMR. It is routinely used for qualitative and quantitative analysis of organic molecules in the liquid state.

Chemical shifts of hydrogen in organic molecules in solution commonly have a range of about 15 ppm of the resonance frequency. For example, protons in common organic molecules in a spectrometer operating at 500 MHz for ^1H will exhibit a chemical shift range of about $15 \times 500 = 7500$ Hz. Scalar couplings to other hydrogen atoms and to carbon atoms are characteristically around 100 Hz. Resolution in commercial liquid state spectrometers is of order of a few tens of hertz, so hydrogen NMR on molecules in the liquid state supplies an easily detectable, well resolved, and sensitive fingerprint for routine analysis.

It was thus initially disappointing that under a single resonant excitation such as was used on liquids, NMR spectra of hydrogen in solids such as ice, or high molecular weight proteins, are broad and featureless. The linewidths are about 15 kHz, an example being given for hydrogen in adipic acid in Figure 1(a).

Exactly those qualities which make ^1H such a valuable label for liquid state NMR destroy the resolution of the NMR spectrum of hydrogen in solids. The reasons are physically

Figure 1 Comparison of NMR spectra taken under: (a) single pulse excitation; (b) MAS at 6 kHz; (c) MAS at 8 kHz; (d) MAS at 11 kHz; (e, f) CRAMPS. (Courtesy of Gary Maciel)

obvious. ^1H is a nucleus with relatively high abundance and large magnetic moment. In a static field it behaves as a magnet, producing a magnetic field with the familiar symmetry exhibited by iron filings aligning in the neighborhood of a bar magnet. In the solid state, each hydrogen atom will be exposed not only to the static field of the magnet used for NMR, but also to the sum of the 'dipolar' fields of all other abundantly present protons in the sample. The result is that the resonance frequency of any hydrogen atom in the sample is homogeneously broadened by the effect of the dipolar fields. In addition, there is NMR line broadening in a motionless solid due to the nonspherical symmetry of the surrounding bonding electronic cloud, i.e. due to 'shielding anisotropies'. CRAMPS was developed to attenuate these two major sources of line broadening such that liquid-like NMR spectra of ^1H and ^{19}F in solids are achieved in favorable cases.

CRAMPS involves manipulations common to NMR of both liquids and solids. These cause the system under observation to vary in time such that chemical shifts become more resolved. Other interactions, e.g. dc field inhomogeneities in liquids, are averaged to small values. A critical fact here is that all observables depend on variables in both real space (r, θ, ϕ), and spin space (components of spin angular momentum, $\hat{I}_k$, $k = x, y, z$) (see *Internal Spin Interactions and Rotations in Solids*). The manipulations used selectively to attenuate

internal interactions which cause a loss of resolution therefore include the following:

1. Sample motion in the laboratory makes θ and ϕ time-dependent. For liquids, spinning rates are roughly 100 Hz. Solids are commonly spun 100 times faster.
2. Radiofrequency (rf) pulsing makes the components of the spin angular momentum operators ($\hat{I}_x$, $\hat{I}_y$, and $\hat{I}_z$) time-dependent.

Rotations in real space,^{4,5} e.g. magic angle spinning, accomplish what molecular tumbling of molecules in the liquid state does for the shielding anisotropy; namely, it averages the anisotropic shielding to its isotropic, or average, value.

Radiofrequency pulses may be thought of as rotating magnetic moments in 'spin space'. We may therefore think of the combined rotation and multiple pulse technique as using rotations in both 'spin space' and in the real space of the laboratory. As understood early on⁶⁻⁸ and shown below, rotations in spin space via rf pulses can be arranged to average local dipolar fields, and the resulting NMR line broadening to values smaller than differences in chemical shifts.

An example of the CRAMPS spectrum⁹ of hydrogen in adipic acid, $\text{HOOC}(\text{CH}_2)_4\text{COOH}$, is shown in Figure 1(e) and (f). Figure 1(b)–(d) show spectra of the static sample under a single pulse excitation, roughly 40 kHz wide, and the spectrum of the sample under magic angle spinning (see below) at frequencies between 6 and 11 kHz. It can be seen that the resolution between the top and the bottom spectrum has increased under CRAMPS by a factor of roughly 600.

In order to illustrate how the experiment works, we first consider how the physical rotation of solid samples narrows the broadening effect of shielding anisotropies. Then we consider how sequences of rf pulses narrow dipolar broadening.

2 ROTATIONS IN REAL SPACE

The most common motion familiar to the NMR spectroscopist working in liquids is that of simply spinning the NMR tube containing the liquid sample about an axis perpendicular to the static field. This partially averages dc field inhomogeneities over the sample volume and improves resolution. Rotation of a liquid at the magic angle further narrows the lines of liquids (see *Magnetic Susceptibility and High Resolution NMR of Liquids and Solids*). The manner in which this works might be perhaps understood by a related example. An individual enthusiastic about the game of football, but without much background in mechanics, constructs a sheet metal wind vane, cut into the shape of an American football. The dynamic balance of this particular device is such that instead of pointing to indicate wind direction, it rotates as the wind blows. For rotation too fast for the eye to follow, the football shaped device, being a thin slice the width of the metal when viewed end-on, and a football shaped object when viewed perpendicular to the surface, seems on average to become something smaller than a football, and something larger than a line. On average, it seems that a circular object is seen. Glancing at the wind vane in a high wind, the builder rapidly blinks at this dysfunction of the device. In doing so, the blinking is unwittingly done in concert with the rotation period of the wind vane, and for an instant, instead of the football shaped wind vane, a very narrow line is seen! Each time the eyes were opened, a

stroboscopic observation was made of the wind vane viewed head-on.

Following the football analogy, consider the symmetry of the bonding electron cloud about an NMR active ^{13}C in a CO_2 molecule, $\text{O}=\text{C}=\text{O}$. Clearly this cloud is roughly football shaped. This bonding electron cloud may be thought to circulate in reaction to the imposition of a static magnetic field, producing a 'shielding field'. The details of the circulation, and thus the shielding field, described in terms of a 'shielding ellipsoid' σ , will be different when the static field is perpendicular to the unique axis of the football than when parallel to it. In fact the shielding field produces an NMR line at $\delta = -90$, i.e. 90 ppm upfield (down frequency; shielded) with respect to ^{13}C in tetramethylsilane (TMS), when the static field is parallel to the unique axis. With the field perpendicular to the unique axis, δ is 245 ppm deshielded with respect to ^{13}C in TMS. In the liquid state, the NMR spectrum of ^{13}C in CO_2 is a narrow line 133 ppm deshielded from TMS. Sufficiently rapid isotropic (random in space) tumbling of the molecule in the liquid results in this football shaped object becoming spherical as viewed by the eye of NMR; the anisotropic shielding is averaged to its isotropic value, which is the average of the three principal axes of the shielding ellipsoid. Note that $133 = (245 + 245 - 90)/3$; the isotropic value of the chemical shift of ^{13}C in CO_2 in the liquid is the average of the values with the dc field along the x , y , and z axes of the shielding ellipsoid.

When the NMR spectrum of carbon dioxide is measured in the powdered, solid state, as dry ice, molecular tumbling is absent. In this case each crystallite contributes an NMR line between 245 ppm and -90 ppm, depending upon the orientation of the shielding ellipsoid in the crystallite to the static field. The total spectrum appears as the 'powder pattern' shown in Figure 2. The weighting of intensity on the high frequency side, corresponding to the static field in the (x, y) plane of the shielding ellipsoid, corresponds to the fact that it is more likely that a given crystallite will have the static field near the (x, y) plane of the shielding ellipsoid than uniquely along the axis of rotation.

The resonance frequency depends on the orientation of the shielding ellipsoid with respect to the static magnetic field, specified by angles θ and ϕ , as shown in Figure 3, and on the asymmetry of the ellipsoid. This asymmetry is uniquely specified by the magnitudes of its three principal axes in ppm

Figure 2 NMR of ^{13}C in powdered solid CO_2 . Illustration of shielding anisotropy for an axially symmetric shielding environment. (Courtesy of Anita Orendt)

Figure 3 Relationship between the principal axes of the shielding ellipsoid and the laboratory coordinate system; definitions of θ and ϕ

of the resonance frequency, denoted by σ_{xx} , σ_{yy} , and σ_{zz} , or in terms of linear combinations of these which more clearly exhibit the symmetry properties. The combinations are

- (a) the average of the magnitudes of the three principal axes, σ_{iso} , the isotropic shielding, which is that quantity observed in NMR of liquids;
- (b) the anisotropy ζ , equal to the difference between σ_{zz} and σ_{iso} ;
- (c) the asymmetry η , proportional to the difference in the x and y components.

We note that a similar ellipsoid describes the anisotropy of the dipolar interaction $\mathbf{D}$ between two nuclei, but in this case the interaction is axially symmetric, $D_{xx} = D_{yy}$, so the asymmetry for the dipolar interaction is zero.

The resonance frequency of a shielding ellipsoid oriented at θ , ϕ with respect to $\mathbf{B}_0$, and with symmetry specified by σ_{iso} , ζ , and η is given by

$$\omega(\theta, \phi, \sigma_{iso}, \zeta, \eta) = \omega_0 \{ \sigma_{iso} + \zeta \left[\frac{1}{2} (3 \cos^2 \theta - 1) + \frac{1}{2} \eta \sin 2\theta \cos 2\phi \right] \} \quad (1)$$

When the sample is set in motion, e.g. by random molecular tumbling, as would take place when the sample is heated to the liquid state, or by sonic agitation of the finely divided solid in a suitable liquid (see *Ultrasonic Irradiation and NMR*), or by the experimenter about an axis oriented at an angle β to the static field, and at a frequency that is fast compared with the spectral width $\omega_0(\sigma_{xx} - \sigma_{zz})$, it may be shown (see *Internal Spin Interactions and Rotations in Solids*) that the averaged frequency becomes only a function of the isotropic chemical shift σ_{iso} , the anisotropy ζ , and the angle β between the spinning axis and the field. This relationship is given by

$$\omega(\omega_0, \beta, \sigma_{iso}, \zeta) = \omega_0 [\sigma_{iso} + \frac{1}{2} \zeta (3 \cos^2 \beta - 1)] \quad (2)$$

The terms in η disappear if the sample is spun rapidly enough, or contribute to sidebands if the spinning rate is smaller than the shielding spectral width. Clearly at the ‘magic’ angle $\beta = \arccos(\frac{1}{3})^{1/2}$, only the isotropic value remains; the

spinning has achieved a liquid-like spectrum by averaging the anisotropic information to zero.

It was recognized early on that MAS could also average the dipolar broadening to zero. However, since all nuclei in a sample rich in protons are connected to all others via the through-space dipolar interactions, it is necessary to spin fast compared with the dipolar linewidth to achieve effective narrowing. This means spinning fast compared with 15 kHz, or fast compared with roughly 10^6 rev min⁻¹. Such spinning speeds are not easily achieved, but have been realized in homemade spectrometers with easily machineable polyimide resins,¹⁰ and are also now available in commercial spectrometers making use of high-precision cylindrical ceramic rotors. A comparison of narrowing under ultrafast MAS and the use of CRAMPS has been made,¹¹ with the conclusion that one would like to have access to both techniques, depending upon the sample. Furthermore, there are spin dynamics containing added information which one may perform using CRAMPS which are not available within the expedient of high speed spinning.

We now consider how manipulating the nuclear spin system with rf pulses averages the dipolar interactions to values smaller than differences in chemical shifts. To do so, we use the background developed in the article *Echoes in Solids*.

3 ROTATIONS IN SPIN SPACE

All spectroscopy experiments implicitly or explicitly involve solutions of the time dependent Schrödinger equation. We have implicitly invoked one such solution in discussing MAS, above. An understanding of NMR appropriate to the level of this Encyclopedia involves at least a rudimentary knowledge of the solutions of this equation in the density operator formulation. Fortunately there are texts for students at both the entry level^{12,13} and advanced levels,^{14–16} presenting both these pictures. As a basis for understanding the multiple pulse portion of the CRAMPS experiment, I briefly summarize the results of selective averaging theory on first the shielding interaction, and then the dipolar interaction. Let us start in the rotating frame of the Zeeman interaction, the frame in the real world in which NMR signals are detected after demodulation removes the carrier frequency from the information content of the signal. In the rotating frame, the principal effective magnetic fields which cause a proton to resonate for detection by NMR are: (a) the externally applied rf field, $\mathbf{B}_1$, and (b) the sample-supplied, or internal average, of the dipolar fields of all other protons, $\mathbf{B}_D$. A smaller perturbation is that of the anisotropic shielding field associated with the reaction to electrons in the environment of the hydrogen nucleus of the static external field.

With each field is associated an energy, and a quantum mechanical energy operator $\hat{\mathcal{H}}$. Thus the energy operator in the rotating frame is given by

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_{rf} + \hat{\mathcal{H}}_{int} \quad (3)$$

where the magnitude of $\hat{\mathcal{H}}_{rf}$ for purposes of solid state experiments is about 5 mT. The magnitude of $\hat{\mathcal{H}}_{int}$ is never greater than a few tenths of a millitesla in the case discussed here—that of homonuclear dipolar coupling. The equation of

motion of the system is then given by the solution to the time dependent Schrödinger equation in the density matrix formulation:

$$i\frac{d\hat{\rho}}{dt} = [\hat{\mathcal{H}}, \hat{\rho}] \quad (4)$$

Here, $\hat{\mathcal{H}}$ is the sum of the rf and internal interactions, as specified in equation (3), $\hat{\rho}$ is the density operator, specified by the wavefunction $|\psi\rangle$, as $|\psi\rangle\langle\psi|$ in Dirac bracket notation. The average values of observables, e.g. $\langle\hat{I}_y(t)\rangle$, the free induction decay detected along the y phase in the rotating frame, are given by

$$\langle\hat{I}_y(t)\rangle = \text{Tr} [\hat{\rho}(t)\hat{I}_y] \quad (5)$$

With the interactions separated in magnitude in this manner, it makes sense to treat $\hat{\mathcal{H}}_{\text{int}}$ as a perturbation on $\hat{\mathcal{H}}_{\text{rf}}$. Recall that the transformation to the frame of the Zeeman interaction (the rotating frame) simplifies the description of a nuclear spin in the presence of other interactions; e.g. the oscillating on-resonance rf field becomes static in the rotating frame. Similarly, transformation to the frame of the now largest interaction, the rf field, further simplifies the description of the system. The transformation to the frame of the rf field is accomplished by the relationships

$$\hat{\rho} = \hat{U}_{\text{rf}}\hat{\rho}\hat{U}_{\text{rf}}^{-1} \quad (6)$$

$$i\frac{d\hat{U}_{\text{rf}}}{dt} = \hat{\mathcal{H}}_{\text{rf}}\hat{U}_{\text{rf}} \quad (7)$$

$$\hat{U}_{\text{rf}}(0, 0) \equiv \hat{U}_{\text{rf}}(t = 0) = \hat{1} \quad (8)$$

$$\hat{\mathcal{H}}_{\text{int}}(t) = \hat{U}_{\text{rf}}^{-1}(t, 0)\hat{\mathcal{H}}_{\text{int}}\hat{U}_{\text{rf}} \quad (9)$$

As mentioned above, the notation $\hat{U}(t, 0)$ is a formal way of saying that the propagator $\hat{U}$ drives the system from time 0 to time t . An explicit operational form of $\hat{U}$ will be given below; for now, accept it as that quantity causing the system to proceed in time, with physical origin in the time-dependent sequence of rf pulses, and the internal interactions as affected by these pulses. The result,

$$i\frac{d\hat{\rho}}{dt} = [\hat{\mathcal{H}}_{\text{int}}, \hat{\rho}] \quad (\text{energy in units of frequency}) \quad (10)$$

is the equation of motion in the frame of the rf field. Now, in the same spirit with which we used the interaction $\hat{\mathcal{H}}$ to transform itself out of the equation of motion [this interaction does not appear in equation (10)] we use the interaction $\hat{\mathcal{H}}_{\text{int}}$ to make another transformation which transforms $\hat{\mathcal{H}}_{\text{int}}$ out of the equation:

$$\hat{\rho} = \hat{U}_{\text{int}}(t, 0)\hat{\rho}\hat{U}_{\text{int}}^{-1}(t, 0) \quad (11)$$

$$i\frac{d\hat{U}_{\text{int}}}{dt} = \hat{\mathcal{H}}_{\text{int}}\hat{U}_{\text{int}} \quad (12)$$

$$\hat{U}_{\text{int}}(0, 0) = 1 \quad (13)$$

Thus $\hat{\rho}$ is replaced by $\hat{\hat{\rho}}$, $\hat{\rho}$ is replaced by $\hat{\hat{\rho}}$, $\hat{U}_{\text{rf}}$ is replaced by $\hat{U}_{\text{int}}$, etc. As shown by equation (14), the system in this frame is static; that is,

$$i\frac{d\hat{\hat{\rho}}}{dt} = [0, \hat{\hat{\rho}}] = 0 \quad (14)$$

We formally identify this static system with the system at time zero; $\hat{\hat{\rho}}$ then becomes identical to $\hat{\rho}(0)$. In this perturbation picture, with $\hat{\mathcal{H}}_{\text{int}}$ being a perturbation on $\hat{\mathcal{H}}_{\text{rf}}$, the motion of the system, is then described by

$$\hat{\rho}(t) = \hat{U}_{\text{rf}}(t, 0)\hat{U}_{\text{int}}(t, 0)\hat{\rho}(0)\hat{U}_{\text{int}}^{-1}(t, 0)\hat{U}_{\text{rf}}^{-1}(t, 0) \quad (15)$$

4 ECHOES AND THE AVERAGE HAMILTONIAN

Before discussing the operational forms of the propagators $\hat{U}$ explicitly, let us examine equation (15) more closely. It is clear that if both $\hat{U}_{\text{rf}}(t_c, 0)$ and $\hat{U}_{\text{int}}(t_c, 0)$ are unity at some particular time t_c , then at this special time it appears that the system has simply not changed, i.e. equations (4) and (15) at time t_c tell us that the value of any observable at this time is the value of that observable's operator at time zero; at time t_c , $\hat{\rho}(t_c) = \hat{\rho}(0)$. There is therefore an enormous simplicity in the behavior of the system which the experimenter may accomplish with proper arrangements of rf pulses, since both $\hat{U}_{\text{rf}}$ and $\hat{U}_{\text{int}}$ depend upon $\hat{\mathcal{H}}_{\text{rf}}$ —the rf pulses which we supply! The fields (5 MT) generated by the rf pulses are much larger than the 'internal fields' due to dipolar and shielding interactions (<0.3 MT). Therefore, as long as $\hat{U}_{\text{rf}}$ operates for times that are short compared with times in which $\hat{U}_{\text{int}}$ affects the system, its motion is predominantly controlled by $\hat{U}_{\text{rf}}$. Then if the sequence of rf pulses generating $\hat{U}_{\text{rf}}(t_c, 0)$ returns the system to its initial state, $\hat{U}_{\text{rf}}(t_c, 0)$ is formally equal to unity, a result inferred from physics rather than mathematics. Examples of such pulse sequences are easily imagined if the physics is kept clearly in mind. For example, the sequence $(\tau, 180^\circ_x, 2\tau, 180^\circ_x, \tau)$ results in a rotation by 2π about the x axis, leaving the system invariant at cycle time t_c equal to time 4τ . The sequence $(\tau, 90^\circ_y, \tau, 90^\circ_x, 2\tau, 90^\circ_{-x}, \tau, 90^\circ_{-y}, \tau)$ has phase alternated pairs of pulses which cancel against each other (the y pulse cancels against the $-y$ pulse, and similarly for x) and leaves the system invariant at a cycle time t_c of 6τ . This phase alternated sequence (for each x , a $-x$, and for each y a $-y$) is a variant of the solid echo sequence¹⁷⁻¹⁹ which became famous as the WAHUA (after John Waugh, Lee Huber, and Ulrich Haeberlen) sequence. Such sequences are said to be cyclic. If these groups of pulses are repeated periodically, they are both cyclic and periodic (see *Average Hamiltonian Theory*). As long as $\hat{U}_{\text{rf}}(nt_c, 0)$ is the dominant propagator, in the 'windows' between these groups of pulses, the system will behave as if it is not moving in time. The

situation is quite analogous to the observation of the spinning football shaped object by the blinking football fan. If the blinking is done in concert with the rotation at such a time that the object is viewed head-on, i.e. when it appears as a thin line, then only a thin line will be seen at all times of observation.

A closer look at equation (15), however, clearly indicates that as time progresses, $\hat{U}_{\text{int}}(nt_c, 0)$ begins to affect the motion of the system. Stroboscopic observation as time progresses, in the windows nt_c , will reveal some motion due to $\hat{U}_{\text{int}}(nt_c, 0)$. Now this propagator, $\hat{U}_{\text{int}}(nt_c, 0)$, is determined by $\hat{\mathcal{H}}_{\text{int}}$. The interaction $\hat{\mathcal{H}}_{\text{int}}$ is the sum of $\hat{\mathcal{H}}_{\text{D}}$ and $\hat{\mathcal{H}}_{\text{CS}}$, the dipolar and shielding interactions as manipulated by the rf pulses. If somehow the dipolar interaction (but not the shielding interaction) can be selectively set in motion so that its time average at times nt_c is zero, the remaining information in the windows of the stroboscopic observation will be the shielding. This is exactly what multiple pulse homonuclear decoupling attempts to accomplish. To see how this works, one needs an explicitly operational form for the internal propagator $\hat{U}_{\text{int}}(nt_c, 0)$. The form is illustrated by the spin echo sequence $(\tau, 180^\circ_y, \tau, 180^\circ_y, \tau)$. In the spin echo sequence, we take the internal Hamiltonian to represent any interaction proportional to the operator $\hat{I}_z$: e.g. shielding, resonance offset, static field inhomogeneities, and scalar couplings to unlike nuclei. Homonuclear dipolar coupling, as shown below, is not proportional to $\hat{I}_z$.

When we manipulate $\hat{\mathcal{H}}_{\text{int}}$ by cyclic and periodic sequences of rf pulses (meaning $\hat{U}_{\text{rf}}(t_c, 0)$ is unity) the form of the propagator $\hat{U}_{\text{int}}$ becomes an exponential,²⁰ with the leading term in the result, stroboscopically observed at cycle times nt_c , given by

$$\begin{aligned} \hat{\rho}(nt_c) &= \hat{U}_{\text{int}}(t_c, 0) \hat{\rho}(0) \hat{U}_{\text{int}}^{-1}(t_c, 0) \\ &= \exp(-i \hat{\mathcal{H}}_{\text{int}}^{(0)} nt_c) \hat{\rho}(0) \exp(i \hat{\mathcal{H}}_{\text{int}}^{(0)} nt_c) \end{aligned} \quad (16)$$

Here, $\hat{\mathcal{H}}_{\text{int}}^{(0)}$, which is equal to the integral over a cycle of the internal Hamiltonian as manipulated in time by the rf pulses,

$$\hat{\mathcal{H}}_{\text{int}}^{(0)} = \frac{1}{t_c} \int_0^{t_c} \hat{\mathcal{H}}_{\text{int}} dt \quad (17)$$

may be interpreted as the time average of this manipulated internal Hamiltonian. The manner of manipulation of $\hat{\mathcal{H}}_{\text{int}}$ is given by:

$$\hat{\mathcal{H}}_{\text{int}}(t) = \hat{U}_{\text{rf}}^{-1}(t, 0) \hat{\mathcal{H}}_{\text{int}} \hat{U}_{\text{rf}}(t, 0) \quad (18)$$

$\hat{\mathcal{H}}_{\text{int}}(t)$ is the instantaneous value of the internal Hamiltonian as determined by the rf pulses. $\hat{U}_{\text{rf}}(t, 0)$ is the propagation operator due to the rf pulses from time zero to time t . For n time intervals $\Delta 1$, followed by $\Delta 2, \dots$, followed by Δn , $\hat{U}_{\text{rf}}$ is clearly the propagator during interval $\Delta 1$, followed by the propagator over $\Delta 2, \dots$, as shown by

$$\hat{U}_{\text{rf}}(t, 0) = \hat{U}_{\text{rf}}(\Delta n) \cdots \hat{U}_{\text{rf}}(\Delta 1) \quad (19)$$

The inverse of this product of matrix operators is given by

$$\hat{U}_{\text{rf}}^{-1}(t, 0) = \hat{U}_{\text{rf}}^{-1}(\Delta 1) \cdots \hat{U}_{\text{rf}}^{-1}(\Delta n) \quad (20)$$

The physical meaning of the exponentials in equation (16) can always be expressed as a product of rotations in spin space acting on components of angular momentum operators. For example, consider the rf pulse sequence with perfect delta function pulses $(\tau, 180^\circ_y, 2\tau, 180^\circ_y, \delta)$ shown in Figure 4. This sequence is used to produce $\hat{\mathcal{H}}_{\text{rf}}$, and thus $\hat{U}_{\text{rf}}$, equal to $\exp(-i \int \hat{\mathcal{H}}_{\text{rf}} dt)$, as indicated in Figure 4.

At times $0 < t < \tau$, when the rf Hamiltonian is zero, $\hat{U}_{\text{rf}}(t, 0)$ takes the form $e^0 = 1$, and in this time interval the value of $\hat{I}_z$ as manipulated by the rf pulse sequence in Figure 4 is given by equation (18). We may physically identify $\hat{U}_{\text{int}}(0 < t < \tau)$ as given in equation (18) with a rotation $\hat{R}$, of unity, performed on $\hat{I}_z$, symbolized by $\hat{R}\hat{I}_z = 1\hat{I}_z$. At time $t = \tau$, the rf Hamiltonian corresponding to the delta function pulse becomes an infinitely fast 180° rotation about the y axis. $\hat{U}_{\text{rf}}(t = \tau) = \exp(i\pi\hat{I}_y)$, and the physical result is a 180°_y rotation $\hat{R}_{180y}$, which sends the operator $\hat{I}_z$ into the operator $-\hat{I}_z$: $\hat{R}_{180y}\hat{I}_z = -\hat{I}_z$. For $\tau < t < 2\tau$ the rf again is zero, and $\hat{U}_{\text{rf}}$ is unity. At $t = 3\tau$, another 180°_y takes place. Under this sequence, therefore, with the spin portion of $\hat{\mathcal{H}}_{\text{int}}$ being proportional to $\hat{I}_z$, and keeping in mind the time ordering dictated by equations (19) and (20), we find the sequence of values of $\hat{I}_z$, the value of $\hat{I}_z$ in the frame of the rf pulses as indicated in Figure 4, and illustrated by the equations

$$0 < t < \tau : \quad \hat{I}_z = e^{-i0}\hat{I}_ze^{i0} = 1\hat{I}_z1 = 1\hat{I}_z = \hat{I}_z \quad (21a)$$

$$t = \tau : \quad \hat{I}_z = 1\hat{R}_{180y}\hat{I}_z = -\hat{I}_z \quad (21b)$$

$$\tau < t < 2\tau : \quad \hat{I}_z = 1\hat{R}_{180y}1\hat{I}_z = -\hat{I}_z \quad (21c)$$

$$t = 2\tau : \quad \hat{I}_z = 1\hat{R}_{180y}1\hat{R}_{180y}\hat{I}_z = \hat{I}_z \quad (21d)$$

$$2\tau < t < 3\tau : \quad \hat{I}_z = 1\hat{R}_{180y}1\hat{R}_{180y}1\hat{I}_z = \hat{I}_z \quad (21e)$$

The familiar result is that at periodic cycle times $4n\tau$, under the spin echo sequence $(\tau, 180^\circ_y, 2\tau, 180^\circ_y, \tau)n$, chemical shifts, and field inhomogeneities, with spin operators $\hat{I}_{zk}$, vanish (but other interactions, such as homonuclear dipolar coupling, do not). This is to say that at cycle times $4n\tau$, with the internal Hamiltonian being proportional to $\hat{I}_z$, $\hat{\mathcal{H}}_{\text{int}}^{(0)}$ is zero, as explicitly shown by

$$\hat{\mathcal{H}}_{\text{int}}^{(0)}(4n\tau) \approx \frac{1}{4\tau} \int_0^{4\tau} \hat{\mathcal{H}}_{\text{int}} dt = \frac{1}{4\tau} \omega_{\text{CS}} [\hat{I}_z\tau + (-\hat{I}_z)\tau] = 0 \quad (22)$$

Here, ω_{CS} is a product of a constant (γB_{eff}) and the portion of the chemical shift Hamiltonian which is a function of the real space angular variables θ and ϕ considered explicitly earlier when talking about magic angle spinning. We may think of observation at periodic cycle times $t = 4n\tau = nt_c$ as observation in the frame of $\hat{\rho}$.

With the basic ideas outlined above, one may now understand how averaging is accomplished for a more complicated internal interaction than one simply proportional to $\hat{I}_z$. One creates periodic groups of cyclic sequences of

Figure 4 Spin echo sequence (τ , 180°_y , 2τ , 180°_y , τ). Cycle time $t_c = 4\tau$. Also indicated are values of $\hat{\mathcal{H}}_{\text{rf}}(t)$, $\hat{U}_{\text{rf}}(t, 0)$, $\hat{I}_z(t) = \hat{U}_{\text{rf}}^{-1}(t, 0) \hat{I}_z \hat{U}_{\text{rf}}(t, 0)$

Figure 5 Dipolar echo sequence (τ , 90°_x , τ , 90°_y , τ). Cycle time $t_c = 3\tau$. Also indicated are the values of $\hat{\mathcal{H}}_{\text{rf}}(t, 0)$, $\hat{U}_{\text{rf}}(t, 0)$, $\hat{I}_z(t)$, $\hat{I}_{z1}\hat{I}_{z2}(t)$, and $\hat{\mathcal{H}}_{zz}(t)$

pulses, such that the propagator due to the rf Hamiltonian $\hat{U}_{\text{rf}}(nt_c, 0)$ is unity, and such that the internal Hamiltonian in question $\hat{\mathcal{H}}_{\text{int}}$ becomes time dependent, i.e. becomes $\hat{\mathcal{H}}_{\text{int}}(t)$, and averages for its time average over a cycle, $(1/t_c) \oint dt \hat{\mathcal{H}}_{\text{int}}(t)$, to be zero. The resulting modulated echo signal in the time domain, when Fourier transformed, yields a spectrum which reflects all other internal Hamiltonians not averaged to zero by the rf pulses.

5 CRAMPS

Applied to the major broadening interaction in proton or in fluorine containing systems, where ^1H or ^{19}F is the only magnetically abundant spin present, the internal interaction

between two protons due to dipolar coupling is given by

$$\hat{\mathcal{H}}_{DII} = \omega_D(\theta)(\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 - 3\hat{I}_{z1}\hat{I}_{z2}) \quad (23)$$

$\omega_D(\theta)$ is the product of a constant and the real space variable θ , the angle between the internuclear vector defining the orientation of the dipole with respect to the external static field. The form need not concern us at this point, except to mention that it must be time-independent. The total dipolar interaction is the sum over all two-body interactions.

Let us denote this two-body interaction by $\hat{\mathcal{H}}_{zz}$, relating to the product of the z components of the two spins in equation (23). Since $\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2$ is a scalar product invariant under rotation, pulse sequences will not affect this part of $\hat{\mathcal{H}}_{zz}$. As shown in Figure 5, a 90°_x pulse at time τ rotates the operator $\hat{I}_z$ into the operator $-\hat{I}_y$, via equation (18).

After this 90°_x pulse, therefore, $\hat{\mathcal{H}}_{zz}$ is transformed into $\hat{\mathcal{H}}_{yy}$. A further 90°_y pulse at time 2τ will be seen, using equations (18)–(20), to result in $\hat{\mathcal{H}}_{zz}$ being transformed into $\hat{\mathcal{H}}_{xx}$. Then at a time $t = 3\tau$ the average homonuclear dipolar Hamiltonian [equation (17)] becomes equal to $(\frac{1}{3}\tau)(\hat{\mathcal{H}}_{xx} + \hat{\mathcal{H}}_{yy} + \hat{\mathcal{H}}_{zz})$, which is zero, i.e. the sum $(\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{z1}\hat{I}_{z2}) + (\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{x1}\hat{I}_{x2}) + (\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{y1}\hat{I}_{y2})$ is equal to $3\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_1 \cdot \hat{I}_2$. This basic dipolar echo sequence ($\tau, 90^\circ_x, \tau, 90^\circ_y, \tau$) is not cyclic, since the system is not returned to its initial value at time 3τ . However, as explained above, the phase alternated sequence in which the 90°_x pulse is followed by a 90°_y pulse, then by a 90°_{-y} pulse, and then by a 90°_x pulse is cyclic, and incorporates two dipolar echo experiments. This is the WAHUA four-pulse sequence. It was first used with stroboscopic observation, as indicated in Figure 6 (see below) to demonstrate that cyclic periodic sequences of rf pulses could lead to averaging of dipolar interactions with resultant detection of much smaller shielding anisotropies. Improved sequences have been developed to remove the loss of resolution associated with experimental artifacts. Two of the best known are the MREV-8 pulse sequence²¹ and the BR-24 pulse sequence.²²

An example of the increase in length of time decay achieved under the BR-24 pulse sequence is shown in Figure 6. Here, the time decay of the magnetization of protons in high density linear polyethylene under the BR-24 sequence, with observation in the first ten windows of the multiple pulse experiment [Figure 6(a)] and a single pulse excitation [Figure 6(b)] are compared. Since the spectral linewidth is proportional to the inverse of the length of the time decay, we see that the resolution under the homonuclear decoupling has been enormously enhanced, the time decay under the BR-24 sequence lasting more than $20\ \mu\text{s}$, and the decay under a single pulse being over in less than 20 ms. Figure 6(c) shows the Fourier transform of the time decay under the BR-24 sequence, illustrating the shielding anisotropy of protons in high density linear crystalline polyethylene. Combined rotation (MAS) and multiple pulse spectroscopy (CRAMPS) would then collapse the shielding powder pattern to its isotropic value, as shown for adipic acid in Figure 1. Thus combined rotation and multiple pulse spectroscopy, based on the above described ideas, when improved a bit by more complicated pulse sequences to remove loss of resolution due to experimental artifacts, e.g. the MREV-8 and the BR-24 sequences, is the basic CRAMPS technique today.

6 CAVEATS

In the above some implicit assumptions have been made which I will make specific at this point.

1. There exist infinitely fast rf pulses which are ' 90° ' pulses.
2. These rf pulses are in fact much larger than any effects of internal interactions.
3. It is possible to place these pulses sufficiently close together such that the times over which they operate cyclically to bring the system back to its initial state is indeed short compared with dephasing times due to internal interactions.
4. It is possible to observe stroboscopically in the windows between these high-powered pulses.

Figure 6 (a) The first ten points of the stroboscopically observed signal of protons in high density linear polyethylene under the BR-24 sequence. (b) FID under a single pulse excitation. Note that the decay under the single pulse excitation is over in roughly $20\ \mu\text{s}$, whereas the decay under the BR-24 lasts longer than 20 ms. Under MAS, the powder pattern, (c) would collapse to a single line, the isotropic value, obtained in the full CRAMPS experiment, as shown for adipic acid in Figure 1

5. Rotation of the sample does not interfere with the averaging due to spin rotations by the rf pulses.
6. The selective averaging of major broadening interactions (dipolar and shielding anisotropy) does not affect the desired interaction—the isotropic chemical shift.

Each of these assumptions is violated in real experiments to a certain extent:

1. There is no infinitely fast pulse. All rf pulses have a finite width, and have transient phase impurities (the 'phase glitch') associated with them, e.g. a 90°_x pulse will have some transient y phase during the turn-on and turn-off periods. In this multiple pulse experiment with stroboscopic observation of the magnetization, errors in pulse flip angle

and pulse phase rapidly accumulate. For example, a 1° error in flip angle, repeated 1024 times, could result in a 90° pulse becoming a 1114° pulse. To achieve 90° pulses which are sufficiently uniform over the entire sample for this experiment, it is necessary to have an rf coil which is long compared with its diameter. In addition, pulses of a given phase always contain transient phase effects which must be cancelled by use of symmetry adapted pulse sequences. These impurities may be treated theoretically as additional internal interactions which may then be averaged by proper selection of rf pulse sequences.²³

2. Radiofrequency fields of 5 mT are not infinitely large compared with dipolar fields of ca. 0.3 mT, but are indeed good enough, as shown in Figure 1.
3. With dipolar interactions causing line broadening of 20 kHz, it is necessary that the time over which the dipolar echo sequence operates is short compared with 50 ms.
4. Achieving the 3τ cycle time of the dipolar echo experiment, which is short compared with 50 ms, with a 500 W amplifier, and a receiver recovery time short enough to allow stroboscopic observation of the motion of the system in the observation window lasting 2τ s, is a result of careful engineering of solid state spectrometers; this facility is not generally available in spectrometers used for liquid state NMR, and in some commercially sold spectrometers for high-resolution solid state NMR.
5. Physical rotation of the sample can indeed interfere with the selective averaging performed by the multiple pulse sequences.²⁴ This interference can produce an extra peak in CRAMPS spectra which is easily recognizable. There are improved pulse sequences being developed which will help reduce this artifact.²⁵
6. The multiple pulse sequences which severely attenuate dipolar broadening also generally affect the isotropic shielding by scaling shielding differences. In general, the scaling factor depends upon the sequence used, and the length of the rf pulses compared with the 3τ cycle time of the dipolar echo sequence. Under the MREV-8, sequence for example, the scaling factor is roughly $\frac{1}{2}$, so that a chemical shift difference of 10 ppm, measured at a spectrometer frequency of 100 MHz for ^1H , does not translate into 1000 Hz in the observed spectrum, but into 500 Hz. Thus resolution is lost. The scaling factor may be easily determined experimentally.²⁴

1 INTRODUCTION

The study of ^2H NMR in the solid state offers one method to probe molecular structure and dynamics in solids. This article will describe the details of the method with particular emphasis on the nature of the quadrupolar coupling of the ^2H nucleus with a surrounding electric field gradient as well as the ^2H NMR spectra and relaxation rates that result from the interaction, particularly in the presence of molecular motion. A few examples will be given to clarify the theoretical explanations given in the text.

The principal utility of studying ^2H NMR in solids is the determination of amplitudes and frequencies of molecular motions in crystalline and amorphous solids. The motions are used to explain macroscopic properties of polymers as well as activation barriers in proteins and crystal packing in small molecules. By choosing appropriate instrumental parameters and experimental conditions, motional timescales spanning more than 10 orders of magnitude can be studied. In particular, 1D lineshape studies can reveal information about molecular reorientation with correlation times τ_c such that $10^{-11}\text{ s} < \tau_c < 10^{-2}\text{ s}$. Longitudinal relaxation of the ^2H nucleus undergoing reorientation is affected when $10^{-7}\text{ s} < \tau_c < 10^0\text{ s}$. The deuteron spin alignment experiment and the related 2D exchange experiment reveal information about molecular motions occurring on very long timescales, up to $\tau_c \sim 10^2\text{ s}$. The combination of these techniques makes ^2H NMR in solids one of the most versatile methods for examining molecular motion.

While ^2H NMR studies of solids offer much promise in molecular dynamics studies, we must consider the following facts. Deuterium is 0.02% naturally abundant, making routine NMR detection really only possible in ^2H -enriched molecules. The NMR resonance frequency is 6.5 times lower than the ^1H frequency, which also affects the sensitivity. Deuterium has nuclear spin $I = 1$, and therefore possesses a quadrupole moment that defines the nonspherical distribution of nuclear charge. The quadrupole moment interacts with the surrounding

electric field gradient, causing a perturbation of the magnetic energy levels of the ^2H nucleus. This quadrupolar interaction can broaden the ^2H resonance to $\sim 200\text{ kHz}$, placing certain demands on the NMR instrumentation used to acquire the data. In spite of these difficulties, ^2H NMR is used routinely in the study of the molecular structure and dynamics of polymer systems, as well as of proteins, lipids, membranes, liquid crystals, and small molecules.

Fortunately, ^2H can be exchanged for ^1H in most systems of interest. Deuterated monomers are readily available for use in the synthesis of polymers. Many lipids are available as the perdeuterated analogs; some can be produced with ^2H incorporated at specific sites in the molecule. Incorporation of ^2H into organisms using deuterated nutrients and D_2O has become a routine method for obtaining deuterated proteins. The use of deuterated amino acids in growth media allows selective incorporation of deuterium as well.

The low magnetogyric ratio of ^2H is not a problem at field strengths of $\sim 4.7\text{ T}$ and above. The availability of NMR instrumentation that allows observation of undistorted spectra over a 200 kHz spectral width has been commercially available for many years. The three main requirements are:¹

1. a transmitter to deliver high-power (1 kW) rf pulses of $\sim 2\text{ }\mu\text{s}$ to excite sufficiently wide bandwidths;
2. a wideband receiver with low distortion filters over the entire spectral width of 200 kHz ; and
3. a high-sensitivity (high- Q) probe with a sufficiently wide bandwidth for the acquisition of distortion-free spectra.

All solid state deuterium NMR pulse sequences are echo sequences due to the wide frequency range of the spectrum. The acquisition of the echo avoids the problem of pulse breakthrough of the FID, leading to severe lineshape distortions. The simplest echo sequence is the two-pulse quadrupolar echo pulse sequence² to refocus the magnetization of a deuterium nucleus. This pulse sequence is shown in Figure 1(a).

Acquisition begins at the midpoint of the echo. One can modify this pulse sequence in various ways to measure ^2H longitudinal relaxation times in solids, deuteron spin alignment echoes and 2D exchange spectra. These modifications are discussed in subsequent sections of this article.

The interpretation of ^2H NMR spectra and relaxation measurements is simplified by the unique properties of the deuterium nucleus. Relaxation is predominantly quadrupolar and allows simplification in dynamic studies of anisotropic molecular motions. To a first approximation, the electronic charge distribution of the ^2H atom is spherically symmetric.³ This results in a well-defined axially symmetric electric field gradient tensor with the principal axis along the $\text{C}-^2\text{H}$ bond.

In the following sections we shall review the ^2H Hamiltonian with emphasis on the quadrupolar interaction and the powder lineshapes of polycrystalline samples which result from quadrupolar echo experiments. The methods used to interpret lineshapes, relaxation times and 2D intensity maps are discussed in subsequent sections, which are organized in relation to the correlation times of anisotropic motions which affect their behavior. A final section is included for completeness which discusses ^2H magic angle spinning in solids and multipulse quadrupolar echoes.

2 THE DEUTERIUM QUADROPOLAR INTERACTION AND THE NUCLEAR SPIN HAMILTONIAN

In order for a nucleus to have a nonspherical charge distribution, its spin must be 1 or greater. Such nuclei, like deuterium with $I = 1$, possess an electric quadrupole moment. The quadrupole moment is a measure of the difference in nuclear charge distribution between the components parallel and perpendicular to z . As a nuclear magnetic moment interacts with an external magnetic field, the electric quadrupole moment interacts with an external electric field gradient. Electrical effects on the energy required to reorient the nucleus are limited to electric field gradients that interact with the ^2H quadrupole moment. Since the electron density of the deuterium atom is spherical to a first approximation, the electric field gradient at a deuterium nucleus is due entirely to the electric charge from proximal atoms.

The coupling energy, E , of a nonspherical ^2H nuclear charge distribution, $\rho_n(\mathbf{r}_n)$, with an electric field gradient arising from the surrounding electronic charges, $\rho_e(\mathbf{r}_e)$, can be described classically by⁴

$$E = \iint \frac{\rho_n(\mathbf{r}_n) \rho_e(\mathbf{r}_e) d^3 r_n d^3 r_e}{|\mathbf{r}_n - \mathbf{r}_e|} \quad (1)$$

By expanding $1/|\mathbf{r}_n - \mathbf{r}_e|$ in terms of the spherical harmonics and replacing the classical charge distributions by quantum mechanical operators⁴ the interaction energy becomes

$$E = \langle \hat{\mathcal{H}} \rangle = \sum_{l,m} e \frac{4\pi}{2l+1} \left\{ \sum_{i=1}^N e_i R_i^l Y_l^m(\Theta_i, \Phi_i) \right\} \times \left\{ \sum_{i=1}^n r_i^{-(l+1)} Y_l^m(\theta_i, \phi_i) \right\} \quad (2)$$

where E is the expectation value of the Hamiltonian $\hat{\mathcal{H}}$; $-e$ is the charge of the electron; R_i , Θ_i and Φ_i are the nuclear coordinates; r_i , θ_i and ϕ_i are the electron coordinates; and $Y_l^m(\Theta_i, \Phi_i)$ and $Y_l^m(\theta_i, \phi_i)$ are the spherical harmonics of the nucleus and electrons, respectively.

Both the nuclear operator, $\{\sum_{i=1}^N e_i R_i^l Y_l^m(\Theta_i, \Phi_i)\}$ and the electronic operator, $\{\sum_{i=1}^n r_i^{-(l+1)} Y_l^m(\theta_i, \phi_i)\}$ are second-rank tensors.⁴

By application of the Wigner–Eckhardt theorem and substitution of the Clebsch–Gordan coefficients⁵ for the nuclear operator, and by rewriting the components of the electronic tensor in the same way, the quadrupole Hamiltonian takes the following form:

$$\hat{\mathcal{H}}_Q = -\frac{1}{6} \sum_{\alpha} \sum_{\beta} \left\{ \frac{\partial^2 V(x, y, z)}{\partial \alpha \partial \beta} \right\} Q_{\alpha\beta} \quad (3)$$

where $\alpha, \beta = x, y, z$,

$$\hat{Q}_{\alpha\beta} = eQ \left\{ \frac{3}{2} [\hat{I}_{\alpha} \hat{I}_{\beta} + \hat{I}_{\beta} \hat{I}_{\alpha}] - \delta_{\alpha\beta} \hat{I}^2 \right\} \quad (4)$$

Q is the classical quadrupole moment, defined by

$$eQ = \int \rho_n (3z_n^2 - r_n^2) d\tau_n \quad (5)$$

$\hat{I}$ is the total deuterium angular momentum operator, and $V(x, y, z)$ is the potential produced at (x, y, z) by exterior charges.

The tensor $V_{\alpha\beta} = [\partial^2 V(x, y, z) / \partial \alpha \partial \beta]$ is symmetric in x, y, z and traceless ($\nabla^2 V = 0$). Therefore, it can be diagonalized by choosing a suitable set of principal axes,⁶ and the deuterium quadrupolar Hamiltonian may be simplified to give

$$\hat{\mathcal{H}}_Q = \frac{eQ}{4} [V_{zz} (3\hat{I}_z^2 - \hat{I}^2) + (V_{xx} - V_{yy})(\hat{I}_x^2 - \hat{I}_y^2)] \quad (6)$$

Only two parameters are necessary to characterize the gradients of the potential: the field gradient, eq , and the asymmetry parameter, η , defined as

$$eq = V_{zz} \quad (7)$$

$$\eta = \frac{|V_{xx} - V_{yy}|}{V_{zz}} \quad (8)$$

The asymmetry parameter measures the departure from cylindrical symmetry of the nuclear charge distribution. For axial symmetry ($V_{xx} = V_{yy}$)

$$\hat{\mathcal{H}}_Q = \frac{eQ}{4}[3\hat{I}_z^2 - \hat{I}^2] \quad (9)$$

and the coupling energies are

$$E(^2\text{H}) = \langle \hat{\mathcal{H}}_Q \rangle = \frac{e^2qQ}{4}[3m^2 - 2] \quad (10)$$

where m is the eigenvalue of $\hat{I}_z$, $I(I + 1) = 2$ is the eigenvalue of $\hat{I}^2$, and $e^2qQ = \chi h$ is called the quadrupole coupling constant.

The quadrupolar energy of a ^2H nucleus can be estimated if one assumes an electronic charge distribution for V . Referring to Gerstein and Dybowski,⁷ the calculation of the quadrupolar energy for a deuterium nucleus is found from $E = eQ|V|/6$ where $e = 4.08 \times 10^{-20}$ esu, $Q = 2.8 \times 10^{-27}$ cm² and $|V| = 8.9 \times 10^{42}$ s⁻¹ cm⁻² esu⁻¹ for a ^2H nucleus next to an electron that is 1 Bohr radius away and opposite a positively charged ion also 1 Bohr radius away. The quadrupolar energy is calculated to be 3.1×10^5 Hz. The quadrupolar coupling constant is proportional to the energy.

For a ^2H nucleus in an applied magnetic field the general form of the Hamiltonian takes the form of the sum of two terms, the Zeeman term and the quadrupolar term:

$$\hbar\hat{\mathcal{H}}(^2\text{H}) = \hbar\hat{\mathcal{H}}_Z + \hbar\hat{\mathcal{H}}_Q \quad (11)$$

The other energy terms which may affect the total Hamiltonian include the chemical shift, dipolar, and spin-spin coupling interactions. Although the magnitude of the ^2H quadrupolar moment is small (2.8×10^{-27} cm²) compared with other quadrupolar nuclei, the quadrupolar energy term dominates in the solid state, and the other contributions can be neglected in the ^2H spin Hamiltonian. (In liquids this is not the case since isotropic reorientation causes the $\hat{\mathcal{H}}_Q$ to vanish). However, the quadrupolar interaction is still dominated by the larger Zeeman interaction ($\hat{\mathcal{H}}_Q \ll \hat{\mathcal{H}}_Z$) at the field strengths typical for this experiment.

A ^2H nucleus, due to its nuclear spin $I = 1$, has three energy states denoted by $m = -1, 0, +1$. In an external magnetic field in the absence of perturbations the allowed transitions between the Zeeman energy levels E_{m+1} , E_{m0} , E_{m-1} lead to degenerate frequencies $\hbar\omega_+ = \hbar\omega_-$. The quadrupolar term $\hbar\hat{\mathcal{H}}_Q$ is given by equation (6), which becomes, in the presence of a large external magnetic field,⁶

$$\hbar\hat{\mathcal{H}}_Q = \frac{\chi h}{8}[(3 \cos^2 \theta - 1) + \eta \sin^2 \theta \cos 2\phi] \quad (12)$$

Figure 2 Energy level diagram for the ^2H nuclear magnetic energy levels showing the perturbation caused by the quadrupole moment

where θ and ϕ are the polar and azimuthal angles relating the principal axis system of the electric field gradient to the external field. For axial symmetry ($\eta = 0$), the total energies are described by

$$E_m = -\gamma \hbar H_0 m + \frac{\chi h}{8}(3 \cos^2 \theta - 1)[3m^2 - 2] \quad (13)$$

The effect of the anisotropic quadrupolar interaction is to remove the degeneracy of the Zeeman levels in the solid state. The two allowed transitions result in a pair of frequencies for each chemically inequivalent deuteron (Figure 2). The separation of the resonance frequencies depends on the angle between the external magnetic field and the z axis of the electric field gradient tensor. From equation (13), $\Delta\nu_q = 3\chi(3 \cos^2 \theta - 1)/4$.

Single crystal studies of deuterated molecules have been used to determine quadrupole coupling constants and relate them to molecular structure.⁴ However, the dynamic information obtained from single crystals is limited, and therefore the study of ^2H NMR powder patterns of polycrystalline and amorphous solids has been more widely used.

3 DEUTERIUM POWDER LINESHAPES: STATIC AND MOTIONALLY AVERAGED

Solid state NMR spectra of single crystals provide valuable information but are impractical or very difficult to obtain for many systems. Additionally, these studies completely ignore amorphous solids. For these reasons it is often desirable to study polycrystalline and amorphous samples to understand their macroscopic behavior. The NMR spectra of spin- $\frac{1}{2}$ nuclei of most polycrystalline solids obtained with no line-narrowing techniques are generally broad, featureless resonances.⁷ In contrast, the ^2H powder spectra of deuterated solids possess a wealth of information about molecular reorientation amplitudes and frequencies. In this section the equations which describe the resulting lineshapes will be developed.

In most cases the deuterium quadrupolar interaction of a carbon-deuterium bond is cylindrically symmetric, with its principal axis lying along the bond axis.³ For this reason we shall concentrate on axially symmetric interactions to develop the equations for the powder lineshapes. We shall see that an axially symmetric lineshape for a static or slowly reorienting moiety can become axially asymmetric in the presence of more

rapid molecular motion. The reader is referred to Haeberlen⁸ and Mehring⁹ for equations describing axially asymmetric ($\eta > 0$) lineshapes.

3.1 Static or Slow Molecular Motion

A ^2H NMR spectrum of a single crystal will show two discrete resonances where the separation in frequency is related to the angle between the principal axis of the quadrupolar tensor and the laboratory frame. In a polycrystalline or amorphous solid, a random distribution of orientation of crystallites occurs where each orientation has equal probability. For deuterated molecules which do not experience reorientation other than librational motion or where the reorientation rate ($1/\tau_c$) of some well-defined motion is less than the quadrupolar coupling frequency, χ , the ^2H powder pattern is described by an axially symmetric tensor. For deuterium in solids one can describe the distribution by an equation relating the angular-dependent frequency to principal axis systems of the quadrupolar interaction and the laboratory frame:⁸

$$\omega_{zz} = \omega_{11} \cos^2 \alpha \sin^2 \beta + \omega_{22} \sin^2 \alpha \sin^2 \beta + \omega_{33} \cos^2 \beta \quad (14)$$

For axial symmetry ($\omega_{11} = \omega_{22} = \omega$, $\omega_{33} = \omega$) equation (14) becomes

$$\omega_{zz} = (\omega_{||} - \omega_{\perp}) \cos^2 \beta + \omega_{\perp} \quad (15)$$

β is the angle between the z axis of the laboratory frame and the z axis of the quadrupolar tensor. $\omega_{\perp}$ is the NMR frequency of those crystallites where the C–D bond axis (and the z -axis of the electric field gradient) is perpendicular to the external magnetic field. Similarly, $\omega_{||}$ corresponds to the frequency where the C–D bond is parallel to the external field.

In a polycrystalline sample the resonance lineshape will be the sum of all the discrete lines and will account for all possible orientations. In order to determine the lineshape it is necessary to calculate the intensity of the resonance lines at each orientation. The intensity, $I(\omega)$, when integrated over a certain frequency interval, $\omega_a \dots \omega_b$, is proportional to the probability of the orientation. $I(\omega)$ can be determined by calculating the area between the curves $\omega = \omega_a$ and $\omega = \omega_b$ on a sphere where the distribution of axially symmetric field gradient tensors is constant:^{8,9}

$$\int_{\omega_a}^{\omega_b} I(\omega) d\omega = c \iint_{\substack{\text{between curves} \\ \omega=\omega_a \text{ and } \omega=\omega_b}} \sin \theta d\theta d\phi \quad (16)$$

Using the normalized frequency $\omega = (\Delta/2)(3 \cos^2 \theta - 1)$, the intensity function becomes^{9,10}

$$I(\omega) = \frac{1}{\sqrt{3}\Delta} \frac{1}{\sqrt{(2\omega/\Delta) + 1}} \quad (17)$$

where $\Delta = \chi$ and ω is defined as $-\Delta/2 < \omega < \Delta$ for one deuterium transition and $-\Delta < \omega < \Delta/2$ for the second deuterium transition.

Figure 3 Theoretical ^2H powder lineshape for a deuteron surrounded by an axially symmetric field gradient. The powder pattern is the sum of the two resonances due to the two allowed transitions of the deuterium nucleus

Equation (17) describes the lineshape for one-half of the deuterium powder pattern. The other half is the mirror image of equation (17) with the center of symmetry at $\omega = 0$. The entire theoretical lineshape for a static C–D bond is plotted in Figure 3.

From Section 2, where the quadrupole interaction energy was calculated to be about 300 kHz, we see that the frequency difference of the perpendicular singularities of the powder pattern is related to the quadrupole coupling constant as $\Delta\omega = 3\pi\chi$. The observed ^2H powder pattern will be line broadened due to the lifetime broadening of the individual frequency components.

For axially asymmetric ($\eta > 0$) quadrupolar tensors, the lineshape becomes

$$f(\omega) = \frac{K(m)}{\pi \sqrt{(\omega - \omega_{11})} \sqrt{(\omega_{33} - \omega_{22})}} \quad \text{for } \omega_{33} > \omega \geq \omega_{22} \quad (18)$$

where $m = (\omega_{22} - \omega_{11})(\omega_{33} - \omega)/(\omega_{33} - \omega_{22})(\omega - \omega_{11})$ and

$$f(\omega) = \frac{K(m)}{\pi \sqrt{(\omega_{33} - \omega)} \sqrt{(\omega_{22} - \omega_{11})}} \quad \text{for } \omega_{22} > \omega \geq \omega_{11} \quad (19)$$

where $m = (\omega - \omega_{11})(\omega_{33} - \omega_{22})/(\omega_{33} - \omega)(\omega_{22} - \omega_{11})$.

In both cases, $K(m) = \int_0^{\pi/2} d\phi [1 - m^2 \sin^2 \phi]^{-1/2}$.

The reader is referred to Haeberlen⁸ and Spiess¹⁰ for a more complete description and analysis of powder lineshapes, including that for an axially asymmetric ($\eta > 0$) quadrupolar tensor.

3.2 Motional Averaging of the ^2H Powder Lineshape

In solids, molecular reorientation can occur at rates as high as 10^{12} s^{-1} at temperatures between 100 and 500 K. Methyl groups are examples for molecular systems which undergo rapid reorientation. Relaxation rates and second moments are affected by the molecular motion, as are ^2H powder lineshapes.

Figure 4 Experimental (a)–(g) and calculated (h)–(n) ^2H NMR spectra of leucine- d_{10} -labeled collagen.¹⁰ The experimental spectra were acquired at the following temperatures: (a) -85°C , (b) -43°C , (c) -18°C , (d) -6°C , (e) $+1^\circ\text{C}$, (f) $+15^\circ\text{C}$ and (g) $+30^\circ\text{C}$. The theoretical spectra were calculated using a two-site jump model with the following reorientation rates: (h) $<6 \times 10^3$ (rad s^{-1}), (i) 1.9×10^4 (rad s^{-1}), (j) 3.1×10^4 (rad s^{-1}), (k) 3.7×10^5 (rad s^{-1}), (l) 6.3×10^5 (rad s^{-1}), (m) 8.7×10^5 (rad s^{-1}), and (n) 1.2×10^6 (rad s^{-1})

If the molecule is undergoing reorientation on a timescale of the order of the quadrupolar interaction or faster, the observed frequencies will be averaged, and the resulting lineshape can be analyzed to determine the rate of motion for a given motional model. One can use this analysis to differentiate between fast diffusion and discrete jump motion.¹¹ This is illustrated in Figure 4 for a collagen sample that is labeled with deuterated leucine (leucine- d_{10}). At low temperatures the lineshape is the expected static axially symmetric powder pattern. As the temperature is increased, the lineshape becomes distorted due to two-site jump motion of the leucine side chain. The equation for the motionally averaged frequency depends on the model used to describe the motion. In fact, many models can be used to describe the same frequency dependence. If one has additional information about the possible motional models, then an estimate of the timescale of motions can be made and related back to the macroscopic properties of the sample.

The lineshape changes are related to the angle through which the C–D bond is reorienting by the relationship⁸

$$\Delta_n = \frac{3\chi}{4}(3\cos^2\gamma - 1) \quad (20)$$

where γ is the angle between the bond vector and the rotation axis.

Rapid reorientation occurs when $1/\tau_c \gg \chi$.

The most lineshape distortion takes place when the reorientation rate ($1/\tau_c$) is of the order of the quadrupole coupling. In those cases the lineshape can be described by⁸

$$I(\omega) = \frac{\kappa(\omega_1 - \omega_2)^2}{4(\omega_1 - \omega)^2(\omega_2 - \omega)^2 + \kappa^2(\omega + \omega_2 - 2\omega_1)^2} \quad (21)$$

where κ is the reorientation rate expressed in radians per second. A complete discussion of the motionally averaged lineshape is given by Haebleren.⁸

4 ANISOTROPIC DEUTERIUM RELAXATION

For deuterium, the spin relaxation is dominated by the quadrupolar interaction, and we need only consider this when interpreting relaxation times. As the lineshapes of deuterium powder spectra yield information about rates of motion for different reorientation models, the deuterium relaxation times also are a source of useful information about models of motion and correlation times. The observed relaxation times can be described by equations relating the reorientation to the spectral density functions involved.

4.1 Longitudinal Relaxation, T_1

The general expression for the spin–lattice relaxation of deuterium is¹²

$$\frac{1}{T_1} = \frac{\omega_Q^2}{3} [J_1^Q(\omega_1) + 4J_2^Q(2\omega_1)] \quad (22)$$

where $\omega_Q = 3\chi/4$.

The spectral density functions are described by¹¹

$$J_m^Q(\omega) = 2 \int_0^\infty C_m^Q(t) \cos(\omega t) dt \quad (23)$$

where $C_m^Q(t)$ is the autocorrelation function that describes the orientation dependence of the quadrupolar tensor as

$$C_m^Q(t) = \langle R_{2m}^{Q*}(0) R_{2m}^Q(t) \rangle / (\rho_{20}^Q)^2 \quad (24)$$

where angular brackets $\langle \rangle$ denote the ensemble average, and $R_{2m}^Q(t)$ and ρ_{20}^Q are elements of the irreducible quadrupole tensor in the laboratory frame and principal axis system, respectively.

The correlation functions for various models of motion have been evaluated by Torchia and Szabo.¹² In particular, by measuring deuterium spin–lattice relaxation times of deuterated methyl groups one can differentiate between free diffusion and three-site jump models of a methyl group undergoing rapid reorientation. For three-site jump motion in the extreme narrowing limit

$$\frac{1}{T_1} = \frac{4\omega_Q^2\tau}{9}(1 + \cos^2\theta) \quad (25)$$

where θ is the angle between the molecular axis system and the external magnetic field. For free diffusion

$$\frac{1}{T_1} = \frac{8\omega_Q^2\tau_1}{27} \quad (26)$$

where there is no θ dependence. In other words, the T_1 shows an orientation dependence for discrete three-site jump

Figure 5 Theoretical behavior of ${}^2\text{H}$ T_1 at 38.45 MHz, plotted as a function of correlation time, $\omega_Q/2\pi = 128.2 \text{ s}^{-1}$. Three-site jumps: $t_c = \text{jump rate}/3$; $\theta = 0^\circ$ (---) and $\theta = 90^\circ$ (- · -). Free diffusion: $t_c = t_1 = 1/\text{diffusion constant}$; $\theta = 0^\circ$ (—) and $\theta = 90^\circ$ (···)

motion but no angular dependence results when the C–D bond undergoes free diffusion (Figure 5).

The equations describing the two orientation-dependent T_1 s for two orientations (parallel and perpendicular) are listed below.¹³

For three-site jumps the equations are

$$\frac{1}{T_1} = \frac{8\omega_Q^2}{81} \left(\frac{\tau_c}{1 + \omega^2\tau_c^2} + \frac{8\tau_c}{1 + 4\omega^2\tau_c^2} \right), \quad \theta = 0^\circ \quad (27)$$

$$\frac{1}{T_1} = \frac{12\omega_Q^2}{81} \left(\frac{\tau_c}{1 + \omega^2\tau_c^2} + \frac{2\tau_c}{1 + 4\omega^2\tau_c^2} \right), \quad \theta = 90^\circ \quad (28)$$

Free diffusion is described by

$$\frac{1}{T_1} = \frac{8\omega_Q^2}{81} \left(\frac{\tau_1}{1 + \omega^2\tau_1^2} + \frac{8\tau_2}{1 + \omega^2\tau_2^2} \right), \quad \theta = 0^\circ \quad (29)$$

$$\frac{1}{T_1} = \frac{4\omega_Q^2}{81} \left(\frac{\tau_1}{1 + \omega^2\tau_1^2} + \frac{2\tau_2}{1 + \omega^2\tau_2^2} + \frac{4\tau_1}{1 + 4\omega^2\tau_1^2} + \frac{2\tau_2}{1 + 4\omega^2\tau_2^2} \right), \quad \theta = 90^\circ \quad (30)$$

4.2 Transverse Relaxation–Anisotropic Deuterium, T_2

Where the reorientation rate of a deuterated molecule is of the order of the quadrupole coupling frequency, the deuterium lineshape is affected by the delays in the pulse sequence.¹⁴ The effect includes intensity losses which are not uniform but frequency dependent across the spectrum. This is due to the anisotropic T_2 which is manifest when the exchange rate or

reorientation rate is comparable to the size of the quadrupolar interaction. The effect becomes more pronounced as the delay between the pulses increases. The T_2 can be determined by measuring the echo amplitude as a function of t_1 , the pulse sequence delay time. In the fast exchange limit and where $t_c \ll t_1$ the equation for the echo amplitude becomes¹⁵

$$K(2t_1) = \exp(-2t_1/T_2) \quad (31)$$

When $t_c \sim \nu_q$, severe distortions and intensity losses result. Using this method one can also distinguish between motional models since the echo distortion varies with different reorientation. The equations dealing with this effect are given by Vega.¹⁵ A very complete treatment of the intensity losses is described by Hirschinger et al.¹⁶ and Shadt et al.¹⁷

5 DEUTERIUM SPIN ALIGNMENT AND 2D EXCHANGE SPECTROSCOPY—THE STUDY OF ULTRASLOW MOTIONS IN DEUTERATED SOLIDS

The two previous sections have dealt with the quadrupolar echo pulse sequence and its utility in determining and interpreting lineshapes for deuterated moieties undergoing medium to fast molecular motions. The lower limit to motions which can be studied using this technique is determined by $1/T_2^*$. In deuterated polymers and other solids, this value is usually about a few hundred microseconds. In order to study ultraslow molecular motions which occur on a timescale slower than $1/T_2^*$, one must choose one of two different experiments. The first technique is the deuterium spin alignment method,^{18–20} which gives accurate information about motions which occur at rates up to a few hundred per second. This experiment uses a three-pulse sequence to generate a spin alignment echo. The echo amplitude decreases as the delay time between the first two pulses increases. The pulse sequence is shown in Figure 1(b). Deuterium spin alignment with three rf pulses leads to a stimulated echo, the amplitude of which is affected by molecular motion. The exchange rate can be determined from the decay of the echo height as a function of t_2 . However, one cannot discriminate between motional models using this technique. The 2D exchange experiment (discussed below) allows one to make that observation.

A more recent technique was developed to give not only information about the rates of molecular motion but also the model for motion as well. This technique combines the spin alignment method with 2D NMR spectroscopy to yield a 2D exchange method for deuterium in the solid state.^{21–25} The pulse sequence required for deuterium 2D exchange spectroscopy is a four-pulse sequence with a mixing period during which frequencies may be exchanged if the mixing time is greater than the correlation time of the motion. The reader is referred to other articles in the Encyclopedia as well as to Ernst et al.²⁶ for a complete detailed explanation of 2D NMR spectroscopy.

One can detect frequency changes accurately if the mixing time is greater than the evolution time and less than T_1 .²² This experiment allows the study of motions with rates from 10^{-3} to 100 s. If one has anisotropic coupling with axial symmetry

Figure 6 Intensity patterns for ^2H 2D exchange powder spectra with an axially symmetric quadrupole coupling tensor undergoing various reorientation angles, θ

($\text{C}-^2\text{H}$), 2D exchange allows model-free determination of the angle through which a deuterated group rotates during the mixing period. The pulse sequence is shown in Figure 1(c).

A brief description of the unique aspects of the pulse sequence used for the deuterium 2D exchange experiment is presented here. The mixing time should be greater than t_c . The phase alternation of the pulse sequence gives rise to two types of echo; the spin alignment echo and the stimulated echo. Appropriate data processing of the two echo signals results in a pure absorption mode spectrum. The 2D map of the ^2H exchange frequencies results in a combination of autocorrelation signals and cross-correlation signals. The autocorrelation signal is the deuterium powder lineshape along the diagonal. The cross-correlation signals depend on the type of motion as well as the amplitude of the motion. The echoes are modulated according to the frequency of the molecular motion that occurs during the mixing period. These modulations lead to off-diagonal intensity in the form of ellipses. One ellipse will be observed for each deuterium transition and for each jump angle represented in the motional model. Therefore, one can determine the number of discrete sites of the reorientation. In the presence of N -site discrete reorientation, the 2D map will have ridges and straight lines which are parallel to the frequency axes. In other words the 2D exchange experiment discriminates between continuous diffusion and discrete jump motion as well as between two-site and four-site jump motion. One can describe the intensity map as an ellipse for each of the two allowed deuterium transitions. The amplitude of the motion is determined from the tangent of the ratio of the semiaxes of the ellipse. A tetrahedral jump

model or four-site hop gives rise to two ellipses for each transition, and a continuous diffusion motion will broaden the ridges of the ellipse with a corresponding decrease in intensity.

The equations describing the ellipses of the deuterium 2D exchange experiment are as follows:²²

$$\Omega_1 - \Omega_0 = \pm \frac{1}{2} \Delta (3 \cos^2 \theta - 1) = \pm \frac{1}{4} \Delta [1 + 3 \cos(2\theta)] \quad (32)$$

and

$$\begin{aligned} \Omega_2 - \Omega_0 &= \pm \frac{1}{2} \Delta [3 \cos^2(\theta \pm \theta_s) - 1] \\ &= \pm \frac{1}{4} \Delta \{1 + 3 \cos[2(\theta \pm \theta_s)]\} \end{aligned} \quad (33)$$

Figure 6 shows a theoretical 2D map of a methyl group undergoing a two-site jump for a variety of angles. Such 2D studies allow the correlation of properties at different times and can separate different properties.

6 OTHER DEUTERIUM NMR EXPERIMENTS IN THE SOLID STATE

It is worth mentioning here some other solid state deuterium NMR experiments used in structure and dynamics studies of polymers and other solids. Although not as widely used as the quadrupolar echo experiment or the 2D exchange method, these experiments are valuable for certain classes of compounds and areas of study.

6.1 Deuterium MAS in Solids^{27,28}

By combining magic angle sample spinning and the deuterium quadrupolar echo experiment one can measure quadrupole coupling constants and asymmetry parameters of nonequivalent deuterons with overlapping powder patterns. The addition of sample spinning also improves the resolution and sensitivity considerably so that one may consider studying unenriched samples. The theory has been developed for static as well as dynamic systems, and the experiment extends the possible dynamic range to study very slow and very fast motions.

6.2 Multiple Pulse Quadrupolar Echoes²⁸

When studying fast or slow motions in deuterated species, one must consider the effects of dipolar coupling, or the resulting lineshapes can be misinterpreted as being due to intermediate exchange processes. Using a four-pulse (MW-4) multipulse sequence²⁹ combined with the quadrupole echo pulse sequence one can distinguish between the intermediate exchange regime and heteronuclear dipolar dephasing. The measurement of the dipolar coupling between protons and deuterons is allowed using this experiment.

6.3 Combined 2D Exchange and Magic Angle Spinning³⁰

A recent experiment that combines magic angle spinning with the 2D exchange pulse sequence provides some interesting intensity maps of deuterated species if no exchange is taking place. In these types of system, if the rotor period is synchronous with the mixing time no cross peaks result (the ridge pattern is lost) and there is a comparable gain in sensitivity. There have been reports of 2D spectra acquired for deuterium in natural abundance using this experiment.³⁰

1 INTRODUCTION

Nuclei which possess the property of spin also have an associated nuclear magnetic moment. It is the interaction between these nuclear magnetic moments and a strong applied magnetic field B_0 which forms the basis of the NMR experiment. This interaction, known as the Zeeman interaction, is always the most important spin interaction for spin- $\frac{1}{2}$ nuclei. In addition to the externally applied magnetic field, nuclei may also experience much smaller internal magnetic fields. For example, the field-induced motion of electrons generates small magnetic fields which modify the applied magnetic field and result in the phenomenon known as nuclear magnetic shielding or chemical shielding. In addition, neighboring nuclear spins may also create small magnetic fields which modify the applied magnetic field. There are two fundamental mechanisms by which one nuclear magnetic moment may interact with another: the *direct* magnetic dipole–dipole interaction and the *indirect* spin–spin interaction. The magnitude of the direct dipolar interaction is directly proportional to the inverse cube of the separation between two spins, while the indirect interaction does not depend on distance in any simple way since it is a two-stage process mediated by the intervening electrons. Because the mechanism of indirect spin–spin coupling involves electrons, this parameter depends on the detailed electronic structure of a molecule. Both the direct and indirect coupling interactions are bilinear in the nuclear spin operators (see below). In principle, the direct dipolar and indirect spin–spin interactions couple every spin of the sample with all others.

Most early NMR investigations were ^1H NMR studies, because of the relatively large magnetic moment of ^1H (hence its high inherent sensitivity to NMR detection), its large natural abundance (99.985%), and its ubiquitous presence in chemical compounds. The direct dipolar interaction has special significance in these studies since proton–proton direct dipolar interactions are largely responsible for the general appearance of ^1H NMR spectra of solid materials. Furthermore, the ^1H – ^1H dipolar interaction provided the first important application of NMR in chemistry. Specifically, Pake¹ used the ^1H – ^1H direct dipolar interaction to determine the H–H separation of water molecules in gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$): $r_{\text{H-H}} = 0.158 \text{ nm}$.

The indirect spin–spin coupling interaction was first observed as magnetic field-independent splittings in the NMR spectra of solution samples.^{2–4} In solution, the direct dipolar interaction averages to zero because of the rapid random tumbling motion of molecules. The first indirect spin–spin coupling constant J was reported by Proctor and Yu in 1951.² It involved the indirect spin–spin coupling between the antimony and fluorine nuclei of the SbF_6^- anion in an aqueous solution of NaSbF_6 ; $J(^{121}\text{Sb}, ^{19}\text{F}) = 1.9 \text{ kHz}$. Shortly after this report, Gutowsky and co-workers reported the observation of $J(^{31}\text{P}, ^{19}\text{F})$ in $\text{P}(\text{O})\text{Cl}_2\text{F}$ (1.2 kHz), $\text{P}(\text{O})\text{ClF}_2$ (1.1 kHz), and $\text{CH}_3(\text{O})\text{PF}_2$ (1.3 kHz).³ The first ^1H – ^1H electron-mediated spin–spin couplings were reported in the same year by Hahn and Maxwell.⁴ They studied the frequency modulation of ^1H NMR spin echoes arising from molecules with chemically nonequivalent hydrogen nuclei. For dichloroacetaldehyde (CHCl_2CHO), two distinct modulation frequencies were observed on the ^1H spin echo envelope: one corresponding to the difference in ^1H chemical shifts, and a second, much smaller frequency J which was independent of the applied magnetic field [$^3J(^1\text{H}, ^1\text{H}) = 0.7 \text{ Hz}$]. On the basis of their measurements, Hahn and Maxwell proposed that the Hamiltonian describing electron coupled spin interactions in isotropic fluids should be of the form $J_{N,N'} \mathbf{I}_N \cdot \mathbf{I}_{N'}$. However, for a pair of coupled spins residing in a molecule which is not rapidly tumbling in an isotropic fluid, Ramsey⁵ later pointed out that the energy of interaction $E_{N,N'}$ depends on the orientation of the spin pair in the applied magnetic field. In general, the energy of interaction is given by

$$E_{N,N'} = h \mathbf{I}_N \cdot \mathbf{J}_{N,N'} \cdot \mathbf{I}_{N'} + h J_{N,N'} \mathbf{I}_N \cdot \mathbf{I}_{N'} \quad (1)$$

where $\mathbf{J}_{N,N'}$ is a second rank tensor whose trace is zero and $J_{N,N'}$ is the isotropic indirect spin–spin coupling constant.

In solid samples, splittings arising from indirect spin–spin coupling were not observed until 1967.⁶ In the solid state, the magnitude of direct dipolar interactions among magnetically abundant spins, such as ^1H or ^{19}F , precluded the measurement of much smaller indirect spin–spin interactions. However, by spinning samples rapidly about an axis inclined at $54^\circ 44'$ with respect to the applied magnetic field, broadening due to anisotropic chemical shielding and direct dipolar interactions can be largely removed. Using this technique, known as magic angle spinning (MAS), Andrew et al.⁶ observed splittings due to $J(^{75}\text{As}, ^{19}\text{F})$ of 905 Hz, and $J(^{121}\text{Sb}, ^{19}\text{F})$ of 1820 Hz in the ^{19}F NMR spectra of solid KAsF_6 and KSbF_6 , respectively. From the ^{19}F NMR linewidths observed in nonspinning samples of these salts, the authors were able to conclude that the hexafluoroarsenate and hexafluoroantimonate anions are dynamically disordered. Rapid jumps of the MF_6 octahedra about their symmetry axes average *intramolecular* dipolar interactions to zero. Subsequently, VanderHart et al.⁷ studied the ^{19}F and ^{31}P NMR lineshapes of static samples of polycrystalline BaFPO_3 where the directly bonded ^{19}F and ^{31}P nuclei are coupled by both the direct dipolar and the indirect spin–spin coupling interactions. The authors indicated that with an accurate value of the ^{19}F – ^{31}P separation r_{FP} , one could calculate the contribution that the direct dipolar interaction makes to the overall ^{19}F or ^{31}P NMR lineshape and, in principle, determine the anisotropy in the indirect spin–spin coupling, a parameter which is usually inaccessible.

The objective of this article is to present an introductory discussion of how spin–spin coupling interactions are described

and how they manifest themselves in the NMR spectra of diamagnetic systems, particularly in NMR studies of solids. The discussion will focus on the indirect spin–spin coupling tensor $\mathbf{J}$, since detailed discussions of the direct dipolar interaction can be found in several textbooks on NMR.^{8–11} For pedagogical reasons, it is most convenient to focus the discussion on simple two-spin systems.

2 DIRECT DIPOLAR COUPLING

A nucleus with nonzero total spin angular momentum $\hbar\mathbf{I}$ also possesses a magnetic moment $\boldsymbol{\mu}$. The magnetic moment and angular momentum vectors are related by the magnetogyric ratio γ , a unique constant for any given isotope:

$$\boldsymbol{\mu} = \gamma\hbar\mathbf{I} \quad (2)$$

It is useful to consider the total static magnetic field emanating from a magnetic dipole. At a point P, the static field depends on the distance r and the angle θ between the magnetic dipole and P; the z component of the local field is $\gamma r^{-3}\hbar(3\cos^2\theta - 1)(\mu_0/4\pi)$. With $\theta = 0^\circ$, the local field 0.1 nm from a proton is 5.64 mT, several orders of magnitude less than the magnitude of typical external fields employed in NMR experiments.

From classical electrodynamics, the energy of interaction E between two magnetic dipoles, $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$, separated by a distance r may be written as

$$E = [(\boldsymbol{\mu}_1 \cdot \boldsymbol{\mu}_2)r^{-3} - 3(\boldsymbol{\mu}_1 \cdot \mathbf{r})(\boldsymbol{\mu}_2 \cdot \mathbf{r})r^{-5}](\mu_0/4\pi) \quad (3)$$

where μ_0 is the permeability constant, $\mu_0 = 4\pi \times 10^{-7} \text{ kg m s}^{-2} \text{ A}^{-2}$. If the two dipoles $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ have the same orientation with respect to $\mathbf{r}$ then equation (3) becomes:

$$E = (\boldsymbol{\mu}_1 \cdot \boldsymbol{\mu}_2)r^{-3}(1 - 3\cos^2\theta)(\mu_0/4\pi) \quad (4)$$

where θ is the angle between the direction of the two magnetic dipoles and the vector $\mathbf{r}$ which separates them.

In NMR studies, one is generally concerned with nuclear magnetic moments. Consider two nuclei (1 and 2) separated by a distance r in a magnetic field (Figure 1). The quantum mechanical Hamiltonian describing the direct dipolar interaction, $\hat{\mathcal{H}}_{\text{DD}}$, is constructed by replacing the vectors $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ in equation (3) by their corresponding operators, $\gamma_1\hbar\hat{\mathbf{I}}_1$ and $\gamma_2\hbar\hat{\mathbf{I}}_2$:

$$\hat{\mathcal{H}}_{\text{DD}} = \gamma_1\gamma_2\hbar^2[(\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2)r^{-3} - 3(\hat{\mathbf{I}}_1 \cdot \mathbf{r})(\hat{\mathbf{I}}_2 \cdot \mathbf{r})r^{-5}](\mu_0/4\pi) \quad (5)$$

where γ_i is the magnetogyric ratio of nucleus i (in $\text{rad s}^{-1} \text{ T}^{-1}$), $\hat{\mathbf{I}}_i$ is the nuclear spin angular momentum operator, and $\mathbf{r}$ is the internuclear vector. In an NMR experiment, the direction of the magnetic moments is defined by the direction of the applied magnetic field $\mathbf{B}_0$.

If one expands the scalar products in equation (5),

$$\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 = \hat{I}_{1x}\hat{I}_{2x} + \hat{I}_{1y}\hat{I}_{2y} + \hat{I}_{1z}\hat{I}_{2z} \quad (6)$$

$$\hat{\mathbf{I}}_1 \cdot \mathbf{r} = \hat{I}_{1x}x + \hat{I}_{1y}y + \hat{I}_{1z}z \quad (7)$$

Figure 1 Coordinate system used to describe the coupling of two spins $\hat{\mathbf{I}}_1$ and $\hat{\mathbf{I}}_2$ separated by a distance r . A strong applied magnetic field lies along the z axis

$$\hat{\mathbf{I}}_2 \cdot \mathbf{r} = \hat{I}_{2x}x + \hat{I}_{2y}y + \hat{I}_{2z}z \quad (8)$$

the direct dipolar Hamiltonian may be expanded and rewritten as

$$\begin{aligned} \hat{\mathcal{H}}_{\text{DD}} = & \gamma_1\gamma_2\hbar^2r^{-5}[\hat{I}_{1x}\hat{I}_{2x}(r^2 - 3x^2) + \hat{I}_{1y}\hat{I}_{2y}(r^2 - 3y^2) \\ & + \hat{I}_{1z}\hat{I}_{2z}(r^2 - 3z^2) - (\hat{I}_{1x}\hat{I}_{2y} + \hat{I}_{1y}\hat{I}_{2x})3xy \\ & - (\hat{I}_{1y}\hat{I}_{2z} + \hat{I}_{1z}\hat{I}_{2y})3yz - (\hat{I}_{1z}\hat{I}_{2x} + \hat{I}_{1x}\hat{I}_{2z})3zx] \\ & \times (\mu_0/4\pi) \end{aligned} \quad (9)$$

This equation can be expressed in matrix form:

$$\begin{aligned} \hat{\mathcal{H}}_{\text{DD}} = & hR \left\{ \begin{bmatrix} \hat{I}_{1x} & \hat{I}_{1y} & \hat{I}_{1z} \end{bmatrix} \right. \\ & \left. \begin{bmatrix} (r^2 - 3x^2)/r^2 & -3xy/r^2 & -3xz/r^2 \\ -3xy/r^2 & (r^2 - 3y^2)/r^2 & -3yz/r^2 \\ -3xz/r^2 & -3yz/r^2 & (r^2 - 3z^2)/r^2 \end{bmatrix} \begin{bmatrix} \hat{I}_{2x} \\ \hat{I}_{2y} \\ \hat{I}_{2z} \end{bmatrix} \right\} \end{aligned} \quad (10)$$

where R is defined as the direct dipolar coupling constant,

$$R = \gamma_1\gamma_2r^{-3}(\hbar/2\pi)(\mu_0/4\pi) \quad (11)$$

Equation (10) can be abbreviated as

$$\hat{\mathcal{H}}_{\text{DD}} = hR(\hat{\mathbf{I}}_1 \cdot \mathbf{D} \cdot \hat{\mathbf{I}}_2) \quad (12)$$

where $\mathbf{D}$ is the direct dipolar tensor.

It is easy to see that if the internuclear vector $\mathbf{r}$, lies along the z axis, then the dipolar tensor becomes diagonal:

$$\mathbf{D} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{bmatrix} \quad (13)$$

This is the so-called principal axis system (PAS) of the dipolar tensor. Note that the principal components of the dipolar tensor

are axially symmetric, i.e. $D_{11} = D_{22}$. From equation (10) it is also obvious that the dipolar tensor is symmetric (i.e. $D_{\alpha\beta} = D_{\beta\alpha}$). Finally, it is also clear that the trace of the dipolar tensor is zero. This result indicates that the direct dipolar interaction does not influence the positions of peaks in liquid phase NMR spectra. It can also be shown that for isolated spin pairs in solid samples the time averaged expectation value of $\hat{\mathcal{H}}_{DD}$ is zero under conditions of MAS.¹² The sample must be spun rapidly with respect to the direct dipolar coupling constant R .

In order to discuss the NMR spectrum of two dipolar coupled spins in the solid state, it is convenient to transform equation (5) from Cartesian coordinates to spherical polar coordinates. This is readily accomplished by setting: $x = r \sin \theta \cos \phi$, $y = r \sin \theta \sin \phi$, $z = r \cos \theta$ and expressing $\hat{I}_x$ and $\hat{I}_y$ in terms of the raising and lowering operators $\hat{I}^+$ and $\hat{I}^-$, respectively:

$$\hat{I}^+ = \hat{I}_x + i\hat{I}_y, \quad \hat{I}^- = \hat{I}_x - i\hat{I}_y \quad (14)$$

Spin functions used to describe a nuclear spin state are eigenfunctions of the Zeeman Hamiltonian; they are often denoted by $|I, m\rangle$, where I is the nuclear spin quantum number and m is the z component of the spin angular momentum in units of $\hbar$ (i.e. $\hat{I}_z |I, m\rangle = m|I, m\rangle$). The spin quantum number m may take on values of $-I, -I + 1, \dots, +I$. Thus, for spin- $\frac{1}{2}$ nuclei there are only two states $|\frac{1}{2}, \frac{1}{2}\rangle$ and $|\frac{1}{2}, -\frac{1}{2}\rangle$, which are generally denoted by $|\alpha\rangle$ and $|\beta\rangle$, respectively: $\hat{I}_z |\alpha\rangle = \frac{1}{2}|\alpha\rangle$ and $\hat{I}_z |\beta\rangle = -\frac{1}{2}|\beta\rangle$, while $\hat{I}^+ |\alpha\rangle = 0$, $\hat{I}^+ |\beta\rangle = |\alpha\rangle$, $\hat{I}^- |\alpha\rangle = |\beta\rangle$ and $\hat{I}^- |\beta\rangle = 0$. Further details concerning the quantum mechanics of angular momentum can be found elsewhere.^{8-11, 13, 14}

In spherical polar coordinates, the dipolar Hamiltonian can be expressed in terms of the so-called dipolar alphabet:

$$\hat{\mathcal{H}}_{DD} = hR(\hat{A} + \hat{B} + \hat{C} + \hat{D} + \hat{E} + \hat{F}) \quad (15)$$

Each of the terms $\hat{A}$ to $\hat{F}$ contains spin operators and a spatial term generally involving both θ and ϕ . Each term alters the spin functions used to describe a spin pair in a characteristic way. Explicit expressions for the terms $\hat{A}$ to $\hat{F}$ are given in several NMR textbooks.⁸⁻¹¹

To describe the NMR spectrum of a pair of equivalent homonuclear spins in a strong magnetic field, it is only necessary to consider the terms $\hat{A}$ and $\hat{F}$:

$$\hat{A} = -\hat{I}_{1z}\hat{I}_{2z}(3\cos^2\theta - 1) \quad (16)$$

$$\hat{B} = \frac{1}{4}[\hat{I}_1^+ \cdot \hat{I}_2^- + \hat{I}_1^- \cdot \hat{I}_2^+](3\cos^2\theta - 1) \quad (17)$$

Clearly, the $\hat{A}$ term does not alter the simple product spin functions $|\alpha\alpha\rangle$, $|\alpha\beta\rangle$, $|\beta\alpha\rangle$, and $|\beta\beta\rangle$ (e.g. $\hat{I}_{1z}\hat{I}_{2z}|\alpha\beta\rangle = (\frac{1}{2})(-\frac{1}{2})|\alpha\beta\rangle$). On the other hand, the $\hat{B}$ term contains the ‘flip-flop’ operator $\hat{I}_1^+\hat{I}_2^- + \hat{I}_1^-\hat{I}_2^+$, which alters the spin functions $|\alpha\beta\rangle$ to $|\beta\alpha\rangle$, and vice versa. For a pair of magnetically equivalent spins which are dipolar coupled in a strong applied magnetic field $\mathbf{B}_0$, the appropriate Hamiltonian operator is

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_{DD} \quad (18)$$

where $\hat{\mathcal{H}}_Z = -\nu_0 h(\hat{I}_{1z} + \hat{I}_{2z})$, and $\nu_0 = \gamma B_0/2\pi$. To describe such a spin system, it is convenient to use the following basis functions:

$$|t_1\rangle = |\alpha\alpha\rangle \quad (19a)$$

$$|t_0\rangle = 2^{-1/2}(|\alpha\beta\rangle + |\beta\alpha\rangle)$$

$$|s\rangle = 2^{-1/2}(|\alpha\beta\rangle - |\beta\alpha\rangle) \quad (19b)$$

$$|t_{-1}\rangle = |\beta\beta\rangle \quad (19c)$$

Using these basis functions, the total matrix of the truncated dipolar Hamiltonian operator is diagonal. The resulting eigenvalues of $\hat{\mathcal{H}}$ (in frequency units) are:

$$|t_1\rangle : -\nu_0 - \frac{1}{4}R(3\cos^2\theta - 1) \quad (20a)$$

$$|t_0\rangle : \frac{1}{2}R(3\cos^2\theta - 1) \quad (20b)$$

$$|t_{-1}\rangle : \nu_0 - \frac{1}{4}R(3\cos^2\theta - 1) \quad (20c)$$

$$|s\rangle : 0 \quad (20d)$$

where θ is the angle between the dipolar vector and the applied magnetic field $\mathbf{B}_0$. Transitions involving the antisymmetric $|s\rangle$ level are symmetry-forbidden; therefore only two transitions, $\nu_0 \pm \frac{3}{4}R(3\cos^2\theta - 1)$, are allowed.

For any general orientation of a spin pair in an applied magnetic field, the two peaks are separated by $(\frac{3}{2})R(3\cos^2\theta - 1)$. Spectra from an isolated homonuclear spin pair in a hypothetical single crystal and powder sample are shown in Figure 2. The powder spectrum, known as a Pake powder pattern, is obtained by considering all orientations of the dipolar vector in $\mathbf{B}_0$ ($0^\circ \leq \theta \leq 180^\circ$; $0^\circ \leq \phi \leq 360^\circ$). The separation between the discontinuities, $(\frac{3}{2})R$, corresponds to $\theta = 90^\circ$ while the shoulders are separated by $3R$, which corresponds to the $\theta = 0^\circ$ orientation.

For a pair of unlike spins A and X, where the two spins have different magnetogyric ratios but both are spin $\frac{1}{2}$, it is only necessary to consider the A term of $\hat{\mathcal{H}}_{DD}$ since this is the only term in the dipolar alphabet which commutes with $\hat{\mathcal{H}}_Z$. The A-spin NMR spectrum consists of two peaks at $\nu_A \pm (\frac{1}{2})R(3\cos^2\theta - 1)$, where $\nu_A = \gamma_A B_0/2\pi$; the X-spin spectrum will be identical, except for the fact that it is centered about ν_X instead of ν_A . For unlike spins, the separation between the discontinuities in the A-spin or X-spin Pake powder pattern is R . If the X spin is a quadrupolar nucleus, calculation of the A-spin NMR spectrum may be more difficult, particularly if the high-field approximation is not applicable [i.e. $\hat{\mathcal{H}}_Z(X) \approx \hat{\mathcal{H}}_Q(X)$]. An instructive example of this problem was provided by Stoll et al.¹⁵ who discussed the ^{13}C NMR spectra of the $^{13}\text{C} - ^{14}\text{N}$ spin pair in a single crystal of $\text{K}_2\text{Pt}(\text{CN})_4\text{Br}_{0.3} \cdot 3\text{H}_2\text{O}$.

In practice, the chemical shielding interaction is orientation dependent, and thus it will also influence the detailed NMR lineshape. For protons, anisotropic chemical shielding generally causes a minor perturbation on the Pake doublet powder pattern, since it will be several orders of magnitude smaller than the direct dipolar interaction. However, for most other nuclei, the anisotropic chemical shielding (in frequency units) may be comparable to or greater than the dipolar interactions with adjacent nuclei. Under such conditions the

Figure 2 Calculated NMR spectra for two equivalent spins $\hat{I}_1$ and $\hat{I}_2$ which interact with one another by the direct dipolar interaction. From top to bottom: calculated spectra for three orientations of the internuclear vector in the applied magnetic field B_0 , $\theta = 0^\circ, 45^\circ, 90^\circ$, respectively. The bottom spectrum is the Pake powder pattern which results from a sum of spectra of individual crystallites which are randomly distributed in the sample. The calculated spectra have been convoluted with a Gaussian function to simulate weak dipolar interactions with more remote nuclei

‘A’-spin NMR spectrum of an AX-spin system in a static powder sample will consist of $2I + 1$ overlapping powder patterns, where I is the spin quantum number of X (Figure 3). One can often obtain valuable information concerning the orientation of chemical shielding tensors by analyzing dipolar chemical shift NMR spectra.^{14,16–18}

Typical values of the direct dipolar coupling constant involving directly bonded spin pairs range from a few hundred hertz to several kilohertz. For example, for the directly bonded ^{13}C – ^{15}N spin pair in the amide fragment of a peptide, $R \approx 1.3$ kHz; for the directly bonded ^{13}C – ^1H spin pair in a typical organic compound, $R \approx 23$ kHz. Further examples of direct dipolar coupling constants involving carbon are given in Table 1.

Much recent research is being focused on recoupling of dipolar interactions in high-resolution MAS experiments, e.g. the rotational resonance and rotational echo double resonance (REDOR) techniques.^{19–21} The objective of these experiments is to determine internuclear separations from small dipolar coupling constants. In fact, as will be outlined in Section 3.2, these experiments yield only an effective dipolar coupling constant

Figure 3 (a) A typical spin- $\frac{1}{2}$ NMR powder pattern of an isolated spin with anisotropic chemical shielding. The principal components of the chemical shielding tensor are easily identified from the powder pattern by the shoulders at σ_{11} and at σ_{33} and the discontinuity at σ_{22} . (b) Same as (a), but the influence of direct dipolar coupling with an adjacent spin- $\frac{1}{2}$ nucleus is illustrated. The direct dipolar interaction causes an apparent splitting of the chemical shielding powder pattern

which is dependent on the anisotropy in the indirect coupling as well as the direct dipolar coupling constant R .

As an aside, it is important to indicate that anisotropic molecular vibrations can result in a subtle vibrationally induced asymmetry of the dipolar coupling tensor; this will be most important when the direct dipolar coupling involves a hydrogen nucleus.^{22,23}

The discussion presented here can be extended to more complex spin systems. For example, Van Hecke et al.²⁴ studied the ^1H and ^{19}F NMR spectra of the bifluoride ion in a single crystal of KHF_2 . In addition, systems containing the $^{13}\text{CH}_2$ fragment have attracted considerable attention.^{25–27}

3 INDIRECT SPIN–SPIN COUPLING

As mentioned in Section 1, indirect spin–spin coupling is a two-stage process. One can imagine the spin at one nucleus perturbing the electrons in its vicinity. The resulting

perturbation is transferred via the electronic framework of the molecule to electrons in the vicinity of the second nucleus. The distinctive ways in which a nuclear moment perturbs the surrounding electrons is known as a mechanism for indirect spin–spin coupling (see below). The total indirect spin–spin coupling constant J is a sum of the contributions arising from each mechanism. Clearly, the contribution that each coupling mechanism makes to J is directly proportional to the product of the nuclear magnetic moments of the two coupled nuclei. The sign of indirect spin–spin coupling constants can be either positive or negative. If the indirect spin–spin coupling interaction stabilizes the antiparallel arrangement of the nuclear spins, then the indirect spin–spin coupling is positive. The magnitudes of isotropic indirect spin–spin coupling constants are readily measured in solution NMR studies. Values as small as 0.10 Hz are routinely measured. Isotropic values rarely exceed 30 kHz; however, a ^{199}Hg , ^{199}Hg indirect spin–spin coupling constant of 139.6 kHz has been reported for the Hg_3^{2+} ion.²⁸ Typical values of one-bond indirect spin–spin coupling constants involving carbon, $^1J(\text{M}, ^{13}\text{C})_{\text{iso}}$, are given in Table 1. The literature on isotropic indirect spin–spin coupling constants is extensive.²⁹ Over the past 45 years many important relationships between spin–spin coupling constants J_{iso} and molecular structure have been established. On the other hand $\mathbf{J}$ tensors are difficult to characterize experimentally. Furthermore, reliable quantum mechanical calculations of $\mathbf{J}$ tensors or their corresponding isotropic values are a challenge.³⁰ Here, the properties of the $\mathbf{J}$ tensor are outlined. This is followed by a discussion of how the $\mathbf{J}$ tensor can be experimentally characterized from solid state NMR measurements.

3.1 Nature of $\mathbf{J}$ Coupling Tensors

The Hamiltonian describing the indirect spin–spin coupling of two spins, $\mathbf{I}_1$ and $\mathbf{I}_2$, may be expressed as

$$\hat{\mathcal{H}}_J = h \hat{\mathbf{I}}_1 \cdot \mathbf{J} \cdot \hat{\mathbf{I}}_2 \quad (21)$$

where $\mathbf{J}$ is the indirect spin–spin coupling tensor. The $\mathbf{J}$ tensor is a second rank tensor which is described by nine matrix elements in a Cartesian coordinate system. For example, in a particular molecular fixed axis system, the $\mathbf{J}$ tensor might be represented by the matrix:

$$\mathbf{J} = \begin{bmatrix} J_{aa} & J_{ab} & J_{ac} \\ J_{ba} & J_{bb} & J_{bc} \\ J_{ca} & J_{cb} & J_{cc} \end{bmatrix} \quad (22)$$

In contrast to the direct dipolar tensor, the $\mathbf{J}$ tensor has a nonvanishing trace.

A general second-rank tensor can be decomposed into a sum of irreducible tensors of rank $l = 0, 1, 2$.^{31,32} Thus the indirect spin–spin coupling tensor can be written as

$$\mathbf{J} = \mathbf{J}^{(0)} + \mathbf{J}^{(1)} + \mathbf{J}^{(2)} \quad (23)$$

In equation (23) the $l = 0$ tensor is the isotropic part of the tensor,

$$\mathbf{J}^{(0)} = \left(\frac{1}{3} \text{Tr } \mathbf{J}\right) \mathbf{1} = J_{\text{iso}} \mathbf{1} \quad (24)$$

where $\text{Tr } \mathbf{J} = (J_{aa} + J_{bb} + J_{cc})$ and $\mathbf{1}$ is the unit tensor with diagonal components equal to 1 and all off-diagonal elements zero. The second term in equation (23), $l = 1$, is the antisymmetric part of the tensor,

$$\mathbf{J}^{(1)} = \frac{1}{2}(\mathbf{J} - \mathbf{J}^t) \quad (25)$$

where $\mathbf{J}^t$ is the transpose of $\mathbf{J}$. The transpose of a 3×3 matrix is obtained by replacing the first column by the first row, the second column by the second row, and the third column by the third row. Since the diagonal elements of $\mathbf{J}$ and $\mathbf{J}^t$ are identical, the diagonal elements of the antisymmetric tensor are zero. The third term in equation (23), $l = 2$, is the symmetric part of the tensor, defined as

$$\mathbf{J}^{(2)} = \frac{1}{2}(\mathbf{J} + \mathbf{J}^t) - J_{\text{iso}} \mathbf{1} \quad (26)$$

Although the trace of the symmetric part is zero, the diagonal elements are, in general, not zero.

To a very good approximation, only tensors with $l = 0$ and $l = 2$ affect the general appearance of an NMR spectrum.³² That is, even though the antisymmetric components of a particular $\mathbf{J}$ tensor may be non zero, these components do not perturb the observed spectrum in first order. In fact, the existence of antisymmetric components in any indirect spin–spin coupling tensor has never been demonstrated experimentally.³³

For each symmetric $\mathbf{J}$ tensor ($\mathbf{J}^{(0)} + \mathbf{J}^{(2)}$), there exists a principal axis system for which the matrix $\mathbf{J}^{(2)}$ is diagonal. The diagonal elements, denoted by J_{xx} , J_{yy} , and J_{zz} , are called the principal elements, with the convention:

$$|J_{zz}| \geq |J_{xx}| \geq |J_{yy}| \quad (27)$$

The principal axis system of the $\mathbf{J}$ tensor is often fixed by the molecular symmetry. For a linear molecule there are only two components, $J_{\parallel}$ and $J_{\perp}$, describing the coupling of the nuclear spin components parallel and perpendicular to the internuclear axis, respectively. Similarly, there are only two non-zero components of the symmetric $\mathbf{J}$ tensor for a pair of nuclei sitting on the highest order symmetry axis of molecules in the point groups D_{nd} , D_{nh} , C_{nh} , C_{nv} , and S_n , with $n \geq 3$. The number of independent components in the $\mathbf{J}$ tensor for other group symmetries has been tabulated by Buckingham et al.³³ and by Robert and Wiesenfeld.³⁴

In describing the orientation dependence of NMR parameters, it is often useful to define the anisotropy of the parameter. This provides a measure of the maximum orientation dependence of that particular parameter. The anisotropy of the indirect spin–spin coupling tensor is usually defined as

$$\Delta J = J_{zz} - \frac{1}{2}(J_{xx} + J_{yy}) \equiv \frac{3}{2}(J_{zz} - J_{\text{iso}}) \quad (28)$$

In the case of axial symmetry, equation (28) simplifies to

$$\Delta J = J_{\parallel} - J_{\perp} \quad (29)$$

In such cases it is straightforward to show that

$$\mathbf{J} = \begin{bmatrix} J_{\perp} & 0 & 0 \\ 0 & J_{\perp} & 0 \\ 0 & 0 & J_{\parallel} \end{bmatrix} = J_{\text{iso}} \mathbf{1} + \begin{bmatrix} -\Delta J/3 & 0 & 0 \\ 0 & -\Delta J/3 & 0 \\ 0 & 0 & 2\Delta J/3 \end{bmatrix} \quad (30)$$

Under these conditions the Hamiltonian equation (21), becomes

$$\hat{\mathcal{H}}_{\mathbf{J}} = hJ_{\text{iso}}\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 + h\hat{\mathbf{I}}_1 \cdot \mathbf{J}' \cdot \hat{\mathbf{I}}_2 \quad (31)$$

where $\mathbf{J}'$ is the traceless ‘ $\Delta\mathbf{J}$ ’ tensor which is of the same form as the dipolar tensor [equation (13)]. Since the trace of $\mathbf{J}'$ is zero, it is clear that the anisotropy in the principal components of $\mathbf{J}$ has no influence on the NMR spectra of isotropic fluids. In principle, ΔJ could provide a mechanism for spin–lattice relaxation, but this mechanism has never been identified as being important.³⁵

Ramsey’s theory⁵ serves as the basis for most theoretical discussions of indirect spin–spin coupling tensors. Following Ramsey, the nonrelativistic Hamiltonian describing nuclear spin, electron spin interactions can be represented by

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}^{(1a)} + \hat{\mathcal{H}}^{(1b)} + \hat{\mathcal{H}}^{(2)} + \hat{\mathcal{H}}^{(3)} \quad (32)$$

The first two terms are the so-called orbital diamagnetic (OD) and orbital paramagnetic (OP) terms which account for the interaction between the nuclear magnetic moments and the orbital motion of the electrons. The third term, $\hat{\mathcal{H}}^{(2)}$, accounts for the spin-dipolar (SD) interactions between the nuclear and electronic magnetic moments. The last term, $\hat{\mathcal{H}}^{(3)}$, accounts for the interaction of the nucleus and the electron spin at the nucleus; this interaction is known as the Fermi contact (FC) interaction. Using these interactions, various approaches, generally based on second-order perturbation theory, are used to calculate indirect nuclear spin–spin coupling tensors. Five separate terms contribute to the overall $\mathbf{J}$ tensor:

$$\mathbf{J} = \mathbf{J}^{(1a)} + \mathbf{J}^{(1b)} + \mathbf{J}^{(2)} + \mathbf{J}^{(3)} + \mathbf{J}^{(4)} \quad (33)$$

The orbital diamagnetic contribution $\mathbf{J}^{(1a)}$ involves only the ground electronic state of the system. The other four terms involve the following combination of interactions: OP–OP, SD–SD, FC–FC, and FC–SD. The OP term has matrix elements between the ground state and excited singlet states while the SD and FC interactions have matrix elements between the ground state and excited triplet states. The FC–FC contribution to the $\mathbf{J}$ tensor is completely isotropic. In contrast, the FC–SD cross term does not contribute to the isotropic value of the spin–spin coupling tensor, but only to its anisotropy, thus the trace of the tensor arising from this term is zero. The other two terms contribute to both the isotropic and anisotropic portion of the total $\mathbf{J}$ tensor.

Explicit expressions for each of the five terms in equation (33) are given in several standard NMR texts and review articles.^{29,36} It should be mentioned that the theory of Ramsey is a nonrelativistic theory which assumes that orbital and spin angular momenta are L – S coupled. Pyykkö³⁷ has developed a relativistic analogue of Ramsey’s theory based on j – j coupling. Undoubtedly, relativistic effects will be important for indirect spin–spin coupling constants involving nuclei beyond the second row. Furthermore, it has been found that consideration of relativistic effects in extended Hückel calculations tends to increase the calculated anisotropy of spin–spin coupling tensors.³⁸

In equation (33), each term is of the form $\gamma_N\gamma_{N'}/h\mathbf{K}_{N,N'}/4\pi^2$, where $\mathbf{K}_{N,N'}$ is called the reduced indirect

spin–spin coupling tensor involving nuclei N and N' . The reduced coupling tensor is independent of the magnitude of the nuclear magnetic moments and, therefore, it is useful in comparing indirect spin–spin coupling tensors involving different spin pairs. Note that $\mathbf{J}_{N,N'}$ has units of Hz (s^{-1}) and $\mathbf{K}_{N,N'}$ has units of $\text{N A}^{-2} \text{m}^{-3}$ (or, equivalently, $\text{T}^2 \text{J}^{-1}$).³⁹ The isotropic indirect spin–spin coupling constants involving carbon in Table 1 have also been expressed as reduced coupling constants. As one descends the group 14 elements, M, of the Periodic Table in the series $\text{M}(\text{CH}_3)_4$, $\mathbf{K}(\text{M},\text{C})$ increases with atomic number Z_M . Similarly, in the series X_3MPR_3 , where M is a group 13 element, $\mathbf{K}(\text{M},\text{P})$ increases as follows: $\approx 10 \times 10^{20} \text{N A}^{-2} \text{m}^{-3}$ ($\text{M} = \text{B}$), $\approx 20 \times 10^{20} (\text{Al})$, $\approx 65 \times 10^{20} (\text{M} = \text{Ga})$, and $\approx 100 \times 10^{20} (\text{M} = \text{In})$.⁴⁰ Qualitatively, these trends can be rationalized by considering only the Fermi contact mechanism; however, there is evidence that the tensor, $\mathbf{K}(\text{In},\text{P})$, in $\text{Br}_3\text{InP}[4-(\text{CH}_3\text{O})-\text{C}_6\text{H}_4]_3$ is anisotropic, implying that mechanisms other than the Fermi contact contribute to this particular $\mathbf{J}$ tensor.⁴⁰

3.2 Measurement of $\mathbf{J}$ Coupling Tensors

Using NMR spectroscopy, $\mathbf{J}$ tensors can be characterized by studying the spectra of single crystals,^{41–43} solid powder samples,^{44–47} or samples oriented in liquid crystalline solvents.^{48,49} In isotropic fluids, only the isotropic indirect spin–spin coupling constant (a scalar) is measured. For simple molecules in the gas phase ΔJ can, in principle, be measured using molecular beam magnetic resonance techniques.⁵⁰ So far, the latter technique has only been successfully applied to thallium fluoride.⁵¹ In this case, $J(^{205}\text{Tl}, ^{19}\text{F})_{\text{iso}} = -13.3 \pm 0.7 \text{ kHz}$ and $\Delta J(^{205}\text{Tl}, ^{19}\text{F}) = 11.1 \pm 0.7 \text{ kHz}$. Below, the NMR spectra of a simple heteronuclear two-spin system residing in a rigid solid will be discussed. Particular emphasis is placed on describing how the NMR spectra depend on ΔJ .

Consider a pair of heteronuclear spins A and X, also denoted by ‘1’ and ‘2’, respectively, which are coupled to one another via direct and indirect spin–spin interactions in a strong applied magnetic field. Furthermore, if the $\mathbf{J}$ tensor is axially symmetric and coincident with the direct dipolar tensor, $J_{\parallel}$ and $J_{\perp}$ correspond to orientations where the internuclear vector is parallel and perpendicular, respectively, to the applied magnetic field. Under these conditions the appropriate nuclear spin Hamiltonian for the A spin is:

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_{\text{CS}} + \hat{\mathcal{H}}_{\text{DD}} + \hat{\mathcal{H}}_J \quad (34)$$

where $\hat{\mathcal{H}}_{\text{CS}}$ accounts for the anisotropic chemical shielding. For now it is assumed that the chemical shielding is independent of the orientation of the molecule in the applied magnetic field. Both $\hat{\mathcal{H}}_{\text{DD}}$ and $\hat{\mathcal{H}}_J$ are of the same form. As already indicated

$$\hat{\mathcal{H}}_{\text{DD}} = hR\hat{\mathbf{I}}_1 \cdot \mathbf{D} \cdot \hat{\mathbf{I}}_2 = -hR\hat{I}_{1z}\hat{I}_{2z}(3\cos^2\theta - 1) \quad (35)$$

Similarly, equation (31) becomes

$$\begin{aligned} \hat{\mathcal{H}}_J &= h\hat{\mathbf{I}}_1 \cdot \mathbf{J} \cdot \hat{\mathbf{I}}_2 = hJ_{\text{iso}}\hat{I}_{1z}\hat{I}_{2z} + h(\Delta J/3)\hat{I}_{1z}\hat{I}_{2z} \\ &\quad \times (3\cos^2\theta - 1) \end{aligned} \quad (36)$$

Using the basic product functions for an AX spin system consisting of two spin- $\frac{1}{2}$ nuclei, it is straightforward to calculate the four energy levels. The A spectrum results from two allowed transitions at:

$$\nu = \nu_A - m_X J_{\text{iso}} + m_X [R - (\Delta J/3)](3 \cos^2 \theta - 1) \quad (37)$$

where $m_X = +\frac{1}{2}$ or $-\frac{1}{2}$. The two A peaks are separated by

$$\Delta \nu = J_{\text{iso}} - [R - (\Delta J/3)](3 \cos^2 \theta - 1) \quad (38)$$

Often, the term $R - (\Delta J/3)$ in equations (37) and (38) is called the effective dipolar coupling constant R_{eff} ; thus,

$$\Delta \nu = J_{\text{iso}} - R_{\text{eff}}(3 \cos^2 \theta - 1) \quad (39)$$

The splittings, $\Delta \nu$, that would be observed as the A-X bond axis, r_{AX} , in a single crystal is rotated about an axis perpendicular to B_0 are shown in Figure 4. Several important points emerge from equations (37)–(39) and Figure 4:

1. For a single crystal sample, equation (39) also applies if the chemical shielding is anisotropic.
2. From Figure 4 it is apparent that the maximum variation in the splitting of the A peaks is $3R_{\text{eff}}$. Experimentally, one cannot separately determine R and ΔJ ; only R_{eff} can be measured. If a value for the internuclear separation r_{AX} can be determined independently by diffraction techniques, R can be calculated from equation (11), and ΔJ can be obtained from the experimental value of R_{eff} .
3. The relative sign of J_{iso} and R_{eff} can be deduced from single crystal measurements. If J_{iso} and R_{eff} have the same sign, the maximum splitting will be $|J_{\text{iso}}| + |R_{\text{eff}}|$, while the minimum splitting will be $|J_{\text{iso}}| - 2|R_{\text{eff}}|$. On the other hand, if J_{iso} and R_{eff} have opposite signs, the maximum splitting will be $|J_{\text{iso}}| + 2|R_{\text{eff}}|$ and the minimum splitting will be $|J_{\text{iso}}| - |R_{\text{eff}}|$.

Figure 4 Separation between the two allowed A spin transitions for an AX spin system in a single crystal as a function of the orientation in the applied magnetic field B_0 . Splittings are given in units of R_{eff} . The rotation axis is perpendicular to B_0 and the rotation angle θ is defined as the angle between r_{AX} and B_0

Figure 5 The effect of ΔJ on the A-spin NMR spectrum of a powder sample containing a heteronuclear AX spin pair. In each case $J_{\text{iso}} = 5R$. With $\Delta J = 3R$, each subspectrum collapses into an isotropic peak

In the case of a powder sample, the A spectrum consists of two subspectra corresponding to $m_X = +\frac{1}{2}$ and $m_X = -\frac{1}{2}$. Each subspectrum is one-half of a conventional Pake powder pattern (Figure 5). The isotropic frequencies of the two subspectra are separated by J_{iso} . (Note that if $J_{\text{iso}} = 0$, conventional Pake powder patterns would be observed except for the case where $\Delta J = 3R$.)

In calculating the spectra shown in Figure 5, the chemical shielding is assumed to be isotropic (i.e. independent of orientation). In order to calculate the A-spin NMR powder lineshape, allowing for the possibility of anisotropic chemical shielding, it is convenient to define the orientation of the internuclear vector in the PAS of the chemical shielding tensor (Figure 6). In this case one can show that the frequency of the A-spin transitions are given by:

$$\nu_m(\theta, \phi) = \nu_L - \nu_{\text{CS}} - m_X \nu_D - m_X J_{\text{iso}} \quad (40)$$

$$\nu_L = \gamma_A B_0 / 2\pi \quad (41)$$

$$\nu_{\text{CS}} = \left(\frac{\gamma_A B_0}{2\pi} \right) (\sigma_{11} \sin^2 \theta \cos^2 \phi + \sigma_{22} \sin^2 \theta \sin^2 \phi + \sigma_{33} \cos^2 \theta) \quad (42)$$

$$\nu_D = R_{\text{eff}} \{ 1 - 3[\sin \beta \sin \theta \cos(\phi - \alpha) + \cos \beta \cos \theta]^2 \} \quad (43)$$

Figure 6 The orientation of an internuclear vector r_{AX} in the principal axis system (PAS) of the A-spin shielding tensor. The angles θ and ϕ define the orientation of B_0 in the PAS of the shielding tensor

where the principal components of the chemical shielding tensor σ_{11} , σ_{22} , and σ_{33} are defined such that $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$. All angles are defined in Figure 6. In deriving equations (40)–(43), it is assumed that the $\mathbf{J}$ tensor is axially symmetric and that the $\mathbf{J}$ and $\mathbf{D}$ tensors are coincident. Even with these assumptions, the A-spin NMR powder spectrum may prove difficult to analyze.¹⁸

From the above discussion, it should be clear that if one is interested in characterizing a particular $\mathbf{J}$ tensor using solid state NMR techniques, single crystal NMR studies are desirable. Unfortunately, few studies have been reported to date.^{41–43} Such studies are generally tedious, require relatively large single crystals (e.g. sides of 1 mm or greater), and the results of an X-ray or neutron diffraction investigation. In some cases, values of ΔJ can be obtained from the analysis of NMR powder spectra which arise from isolated spin pairs.^{44–47} For example, for a series of mercury phosphine complexes values of $\Delta J(^{199}\text{Hg}, ^{31}\text{P})$ of the order of 5 kHz have been estimated from the analysis of static ^{31}P NMR spectra.^{46,47} Below, the general procedure used to analyze such spectra is outlined.

The ^{31}P CP MAS spectrum of one of these complexes, $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$, is shown in Figure 7. The natural abundance of ^{199}Hg is 16.84% ($I = \frac{1}{2}$), therefore the ^{31}P NMR spectrum of the molecules containing the ^{199}Hg – ^{31}P spin pair is a doublet with separation $J(^{199}\text{Hg}, ^{31}\text{P})_{\text{iso}} = 9660$ Hz. The sign of this indirect spin–spin coupling constant is assumed to be positive on the basis of double resonance NMR experiments carried out on related molecules in solution. The only other naturally occurring isotope of mercury with nonzero spin is ^{201}Hg ($I = \frac{3}{2}$; natural abundance 13.22%), but the ^{31}P NMR spectrum of the ^{201}Hg – ^{31}P spin pair is very broad and difficult to observe at room temperature. Molecules containing other naturally occurring isotopes of mercury give rise to a single isotropic peak, since the mercury nuclei of these isotopes have $I = 0$. In order to obtain R_{eff} , it is most advantageous to obtain a ^{31}P NMR spectrum of a static powder sample (Figure 8). Again, the intense central feature in the ^{31}P NMR spectrum corresponds to molecules where mercury nuclei have a spin $I = 0$.

Analysis of this central lineshape provides the principal components of the phosphorus shielding tensor, information required to analyze the subspectra arising from the ^{199}Hg – ^{31}P spin pairs. In this case, the phosphorus shielding tensor is

Figure 7 The ^{31}P NMR spectrum of a powder sample of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ obtained with relatively slow magic angle sample spinning ($\nu_r = 892$ Hz). The spectrum was obtained with high-power ^1H decoupling and cross polarization in an applied magnetic field of 4.7 T, corresponding to a ^{31}P NMR Larmor frequency of 81.0 MHz. Frequencies are given with respect to the isotropic ^{31}P NMR peak of solid $\text{NH}_4\text{H}_2\text{PO}_4$. The horizontal arrow indicates the separation between the isotropic peak positions of the ^{199}Hg satellite peaks ($J_{\text{iso}} = 9660$ Hz). Note that the spinning sidebands of the high-frequency satellite peak, $m_{\text{Hg}-199} = -\frac{1}{2}$, extend over a much larger range than do those of the low-frequency satellite corresponding to $m_{\text{Hg}-199} = \frac{1}{2}$

Figure 8 The ^{31}P NMR spectrum of a static powder sample of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ obtained at 81.0 MHz

approximately axially symmetric with the unique component along the Hg–P bond axis. Inspection of the spectrum shown in Figure 8 indicates that the high-frequency subspectrum corresponding to $m_{\text{Hg}-199} = -\frac{1}{2}$ is stretched (breadth ≈ 4.75 kHz), while the low-frequency subspectrum corresponding to $m_{\text{Hg}-199} = \frac{1}{2}$ is squeezed (breadth ≈ 1.45 kHz) relative to the intense central powder pattern [$(\nu_{\parallel} - \nu_{\perp}) \approx 3.10$ kHz]. In this particular case it is straightforward to show that the

Figure 9 Calculated ^{31}P NMR powder spectra of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ as a function of ΔJ . The direct dipolar coupling constant, $R = 0.64$ kHz, and $(\nu_{\parallel} - \nu_{\perp}) \approx 3.10$ kHz were held constant in each calculation. The central uncoupled ^{31}P NMR spectrum is only shown in the top spectrum; its intensity has been suppressed to emphasize the variations in the satellite subspectra as a function of ΔJ

breadth of each subspectrum is given by

$$\Delta\nu_{\pm m(\text{Hg}-^{199})} = (\nu_{\parallel} - \nu_{\perp}) \pm 3m_{\text{Hg}-^{199}}R_{\text{eff}} \quad (44)$$

Solving equation (44), one obtains $R_{\text{eff}} = -1.10$ kHz. From the known values of $r_{\text{Hg}-\text{P}}$ in closely related compounds, $R = 0.64$ kHz; thus $(\Delta J/3) = 1.74$ kHz and $\Delta J = 5.2$ kHz. Note that if the relative signs of R_{eff} and J_{iso} were not known, another acceptable solution would be $R_{\text{eff}} = +1.10$ kHz, hence $\Delta J = -1.38$ kHz. The sensitivity of the ^{31}P NMR spectrum of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ to ΔJ is illustrated in Figure 9. A complete single crystal ^{31}P NMR study of a closely related compound, $\text{HgP}(\text{cyclohexyl})_3(\text{NO}_3)_2$, has recently been completed.⁵² A typical rotation pattern is shown in Figure 10. Analysis indicates that $R_{\text{eff}} = -1.07$ kHz, leading to comparable values of $\Delta J(^{199}\text{Hg}, ^{31}\text{P})$.⁵² The results of these studies are significant in that they indicate that mechanisms other than the Fermi contact contribute to the $\mathbf{J}(^{199}\text{Hg}, ^{31}\text{P})$ tensor.

For AX spin systems in powder samples, one can also obtain R_{eff} from slow spinning MAS or variable angle spinning NMR studies; however, the errors tend to be large. Therefore, unless R_{eff} is significantly different than R , any estimate of ΔJ may be meaningless.

If a spin- $\frac{1}{2}$ nucleus is coupled to a neighboring quadrupolar nucleus, the spin- $\frac{1}{2}$ MAS NMR lineshape will often exhibit

Figure 10 Plot of $\Delta\nu - J(^{199}\text{Hg}, ^{31}\text{P})_{\text{iso}}$ versus the rotation angle for a single crystal of $\text{HgP}(\text{cyclohexyl})_3(\text{NO}_3)_2$. In this case the rotation axis is approximately perpendicular to the vector $r_{\text{Hg}-\text{P}}$ so that the maximum observed variation in frequency (3.21 kHz) is approximately $3R_{\text{eff}}$

residual ‘dipolar splittings’ due to coupling with the quadrupolar nucleus.⁵³ In such cases the magic angle is no longer ‘magic’ because of the breakdown of the high-field approximation. Qualitatively, the Zeeman states of the quadrupolar nuclei are perturbed by the quadrupolar interaction. Thus, the detailed spin- $\frac{1}{2}$ MAS NMR lineshape depends on R_{eff} , B_0 , the nuclear quadrupolar coupling constant, and the orientation of the EFG tensor at the quadrupolar nucleus with respect to R_{AX} . Unless information concerning the EFG tensor at the quadrupolar nucleus is available from independent NMR or NQR studies, analysis of the spin- $\frac{1}{2}$ MAS NMR spectrum will be problematic.

Information concerning ΔJ is also available from NMR studies of solute molecules partially ordered in liquid crystalline solvents; however, again one can only determine R_{AX} . In fact, from such experiments one measures a parameter which is related to $-S_{zz}[R - (\Delta J/3)]$, where S_{zz} is an order parameter, typically of the order of 0.1. In addition, it is necessary to make vibrational corrections and consider solute–liquid crystal solvent interactions. In spite of these problems, reliable values of ΔJ appear to be available for several compounds. For example, for methyl fluoride, $\Delta J(^{19}\text{F}, ^{13}\text{C}) = 404 \pm 31$ Hz, and thus $\Delta J(^{19}\text{F}, ^{13}\text{C})/J(^{19}\text{F}, ^{13}\text{C})_{\text{iso}} = -2.5 \pm 0.2$;⁵⁴ for dimethylmercury, $\Delta J(^{199}\text{Hg}, ^{13}\text{C}) = 855 \pm 14$ Hz, and thus $\Delta J(^{199}\text{Hg}, ^{13}\text{C})/J(^{199}\text{Hg}, ^{13}\text{C})_{\text{iso}} = 1.25 \pm 0.02$.⁵⁵

As mentioned in Section 2, several NMR experiments have been developed to recouple the direct dipolar interaction under conditions of MAS. Although such experiments actually measure R_{eff} , and not R , it is probably reasonable to assume that $(\Delta J/3) \ll R$, if the coupled nuclei are both first row elements (e.g. ^{13}C and ^{15}N), where J_{iso} is probably at least an order of magnitude less than R . Clearly, reliable theoretical calculations could be of value in assessing the validity of this assumption for any given spin pair.

Finally, it is of interest to mention that, several years ago, Andrew and Farnell⁵⁶ investigated the effect of magic angle sample spinning on each of the irreducible tensors which describe the indirect spin–spin coupling tensor [equation (23)]. Of course, MAS does not influence the term $\mathbf{J}\mathbf{1}$; also, the traceless symmetric components do not influence

the MAS spectrum. However, for a homonuclear spin pair, they found that MAS will not necessarily result in a complete averaging of the antisymmetric components of the $\mathbf{J}$ tensor [i.e. components of $\mathbf{J}^{(1)}$ in equation (23)]. The contribution of the antisymmetric components was predicted to be most important when the chemical shift difference between the two coupled spins was very small. Further discussions of the possibility of measuring antisymmetric components of the $\mathbf{J}$ tensor are given in the excellent review by Robert and Wiesenfeld.³⁴ As already mentioned, the antisymmetric components of any indirect spin–spin coupling tensor have not been experimentally characterized.

4 SUMMARY

From the experimental point of view, it is clear that the mathematical properties of the anisotropic indirect $\mathbf{J}$ tensor are analogous to those of the direct dipolar tensor. As a result, it is impossible to measure separately the anisotropic $\mathbf{J}$ tensor and the direct dipolar tensor. Fortunately, for isolated spin pairs in rigid solid samples, the direct dipolar tensor can always be calculated if structural data are available. The most reliable procedure for characterizing $\mathbf{J}$ tensors in the solid state involves single crystal NMR experiments. For solid powder samples the determination of ΔJ is often problematic. The reliability of a powder analysis will always be greatest when: (i) the spin pair of interest lies along a symmetry axis, (ii) J_{iso} is large enough so that the individual subspectra are well resolved, and (iii) R is small or at least comparable to $\Delta J/3$. With the availability of higher sensitivity NMR hardware and advanced single crystal NMR experiments one can hope that more reliable experimental data will become available. In the future, one can also anticipate significant advances in computational techniques, particularly for relatively small molecules involving atoms of the first two rows of the Periodic Table. Unfortunately, these are the systems where it is most difficult to obtain reliable experimental data concerning the anisotropy in the $\mathbf{J}$ tensor. In any case, it is clear that in order to formulate meaningful models relating J couplings to molecular structure, a better understanding of the $\mathbf{J}$ tensor is essential. Obviously, any information that indicates which mechanisms are or are not operative is critically important in leading to a better understanding of J coupling phenomena.

1 INTRODUCTION

The application of dipolar spectroscopy as a structural tool in solids can be realized with the help of transient nutations and other similar techniques. The main objective is to take advantage of the unambiguous geometric and dynamical interpretation of purely homonuclear dipolar spectra involving a small number of interacting spins. Thus, the requirements to be met not only involve the removal of broadening caused, for example, by shielding interactions and static field inhomogeneities, but also that homonuclear dipolar couplings remain either unchanged or are affected in a easily accountable way.

Dipolar spectroscopy in solids using transient nutations was pioneered by Yannoni and Kendrick¹ as a method for obtaining structural information in systems where the lack of some degree of long-range order excludes the use of diffraction techniques. The method, which involves enrichment of an isotopically rare spin- $\frac{1}{2}$ nucleus at two selected molecular positions, followed by dilution of the pairs either in the unenriched material or in a matrix, is ideally suited for structural studies in amorphous solids, reaction intermediates, catalysts, etc.

Transient nutation is just one of the available strategies for dipolar spectroscopy in solids. The suppression of inhomogeneous broadening can also be achieved by employing a train of properly chosen rf pulses. Of the possible pulse sequences, the venerable Carr–Purcell sequence² and its variations, with some additions and corrections, has also been shown³ to be quite effective as a structural tool in disordered solids, giving some advantage in overall spectral resolution.

2 DIPOLAR SPECTROSCOPY OF ISOLATED PAIRS

In order to extract useful geometrical and dynamical information in disordered solids from the homonuclear magnetic dipole–dipole interaction, it is required that the spectra contain sharp and well-defined features, even when the dipoles

are randomly oriented. This can be achieved, for example, by creating small clusters of mutually interacting dipoles through isotopic enrichment and matrix isolation or dilution. The simplest strategy is to attempt to approximate a regime of isolated pairs.

For a pair of identical nuclear spins I_1 and I_2 and magnetogyric constant γ in a strong magnetic field $B_0 = \omega_0/\gamma$ along the z axis, the secular⁴ Hamiltonian $\hat{\mathcal{H}}_{12}$ involving Zeeman and dipolar interactions can be written as

$$\hat{\mathcal{H}}_{12} = -\hbar\omega_0(\hat{I}_{z1} + \hat{I}_{z2}) + A_{12}(\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{z1}\hat{I}_{z2}) \quad (1)$$

where

$$A_{12} = \hbar^2\gamma^2(3\cos^2\theta_{12} - 1)/2r_{12}^3 = \hbar^2\gamma^2 P_2(\cos\theta_{12})/r_{12}^3 \quad (2)$$

$P_2(\cos\theta_{12})$ in equation (2) denotes a second-order Legendre polynomial, r_{12} represents the internuclear vector, and θ_{12} is the angle between r_{12} and B_0 .

The eigenfunctions and eigenvalues of $\hat{\mathcal{H}}_{12}$ for spin- $\frac{1}{2}$ nuclei can be verified from equation (1) to be the triplet states $|t_{\pm}\rangle = |+\rangle|+\rangle$, $|t_{-}\rangle = |-\rangle|-\rangle$ and $|t_0\rangle = (|+\rangle|-\rangle + |-\rangle|+\rangle)/\sqrt{2}$, with energies $E_{t+} = \hbar\omega_0 + A_{12}/2$, $E_{t-} = -\hbar\omega_0 + A_{12}/2$, and $E_{t0} = -A_{12}$, respectively, and the singlet state $|s_0\rangle = (|+\rangle|-\rangle - |-\rangle|+\rangle)/\sqrt{2}$ with energy $E_{s0} = 0$. Since the latter is not connected to the triplet states by a rf magnetic field, the spectrum consists of only two lines, the famous Pake⁵ doublet, with a frequency separation given by:

$$\begin{aligned} \delta\nu_p &= 3\hbar\gamma^2(3\cos^2\theta_{12} - 1)/4\pi r_{12}^3 \\ &= 3\hbar\gamma^2 P_2(\cos\theta_{12})/2\pi r_{12}^3 \end{aligned} \quad (3)$$

Most important as a structural tool in systems lacking long-range order is the spectrum of randomly oriented isolated pairs of spin- $\frac{1}{2}$ nuclei. It can be obtained from equation (3) under the assumption of vectors r/r uniformly distributed on a unit sphere. The spectral weight in the frequency interval $d\nu$ is then proportional to the solid angle $2\pi \sin\theta d\theta$ and to $1/(d\nu/d\theta)$, where $\nu - \nu_0 = \pm\delta\nu_p/2$ [equation (3)] are the positions of the two members of the Pake doublet relative to the Larmor frequency $\nu_0 = (\gamma/2\pi)B_0$. Thus, the frequency spectrum for randomly oriented⁵ isolated pairs can be seen to be proportional to $1/|\cos\theta|$ and, consequently, to display singularities for $\theta = \pi/2$ corresponding to $\nu - \nu_0 = \pm 3\hbar\gamma^2/8\pi r_{12}^3 = \pm\Delta_p/2$.

Not only can useful geometrical information be obtained from a spectrum of isolated pairs (Figure 1), but also a description of the dynamics. If the internuclear vector r_{12} is assumed to execute a hindered rotational motion reorienting about a fixed direction in space by random jumps between several positions, the changes in the spectrum shown in Figure 1 can be accurately predicted from the postulated dynamical model for the motion.⁶ Moreover, if the reorientation rate is fast compared with $\delta\nu_p$ [equation (3)], a simple average of $P_2(\cos\theta_{12})$ can be performed in order to determine the changes in the spectrum corresponding to this fast motional regime. If the fixed polar angle of B_0 relative to the reorientation axis is denoted by Γ , and the constant angle between r_{12} and the reorientation axis is denoted by ψ_{12} , the addition theorem for spherical harmonics

Figure 1 Spectrum of randomly oriented isolated pairs of dipolar-coupled spin- $\frac{1}{2}$ nuclei. The frequency separation between the singularities in the distribution of Pake doublets has the value $\Delta_p = 3\gamma^2\hbar/4\pi r_{12}^3$

can be used to perform the average $\langle P_2(\cos \theta_{12}) \rangle$ over the time-dependent azimuthal angle associated with $\mathbf{r}_{12}$, yielding⁷

$$\langle P_2(\cos \theta_{12}) \rangle = P_2(\cos \Gamma)(3 \cos^2 \psi_{12} - 1)/2 \quad (4)$$

Equation (4) is valid in the fast motion limit, for hindered rotation between positions of three-fold or higher symmetry, regardless of the details of the motion.

One concludes from equations (3) and (4) that the spectrum corresponding to random directions of the reorientation axis remains identical to the rigid case (Figure 1), but its width can be seen from equation (4) to be reduced by the factor $(3 \cos^2 \psi_{12} - 1)/2$.

3 SUPPRESSION OF OTHER BROADENING INTERACTIONS

In order to use dipolar spectra of isolated pairs as a structural tool, one needs to suppress other couplings. For spin- $\frac{1}{2}$ nuclei, heteronuclear dipole–dipole interactions, broadening by anisotropic chemical shifts or Knight shifts, and susceptibility broadening in small metallic particles, are among the most frequently found interactions that can mask the spectrum of dipole–dipole coupled isolated pairs.

3.1 Coherent Averaging

As a first step, the choice of an appropriate sequence of pulses for suppressing these couplings without affecting the homonuclear dipolar interactions is worth examining within the framework of average Hamiltonian theory.⁸ For δ function excitation pulses, the evolution of the density operator in the rotating frame in the limit of closely spaced pulses has been shown to be governed, after many cycles, by an average Hamiltonian:

$$\hat{\mathcal{H}} = (1/T) \sum_{k=1}^n \hat{\mathcal{H}}_{nk} \tau_k \quad (5)$$

where τ_k represents the time interval between the k th and the $(k + 1)$ th pulse in a cycle consisting of n pulses with period $T = \sum_{k=1}^n \tau_k$. The $\hat{\mathcal{H}}_{nk}$ values in equation (5) can be controlled by the experimenter by a suitable choice of pulses, adequate to the particular internal interactions present.

For the Carr–Purcell sequence, one has $n = 2$ and $\tau_1 = \tau_2 = 2\tau$. Representing the π pulses by the spin rotation operators $\hat{P}_1 = \hat{P}_2 = \exp(-i\pi \hat{I}_y)$ it can be shown⁸ that the average Hamiltonian reduces to:

$$\hat{\mathcal{H}} = \frac{1}{2}(\hat{\mathcal{H}} + \hat{P}_2 \hat{\mathcal{H}} \hat{P}_2^{-1}) \quad (6)$$

which satisfies the requirements for dipolar spectroscopy. Terms in $\hat{\mathcal{H}}$ corresponding to various types of shifts have the general form:

$$\hat{\mathcal{H}}_S = \sum_i \Delta\sigma_i \hat{I}_{zi} \quad (7)$$

where, for the case of secular chemical shifts, the shielding anisotropy $\Delta\sigma_i$ terms depend upon the orientation of the principal axes of the shielding tensor⁸ at the i th site relative to $\mathbf{B}_0$. From equation (7) it is clear that $\hat{\mathcal{H}}_S = 0$, since the π pulses represented by $\hat{P}_2$ in the second term of the equation simply change the sign of $\hat{\mathcal{H}}_S$. On the other hand, the homonuclear dipolar interaction [equation (1)], being bilinear in the individual spin operators, remains unaffected.

Although the secular heteronuclear interaction is also linear in the individual $\hat{I}_{zi}$ operators and can also be suppressed by the Carr–Purcell sequence and its variations, it is generally more convenient in practice to use strong rf irradiation at the Larmor frequency of these spins for an effective decoupling from the resonant nuclei.

Other pulse sequences also satisfy the requirements for dipolar spectroscopy. For example, several variations of the Carr–Purcell sequence have been proposed in order to compensate for the cumulative error caused by imperfect π pulses. In the Carr–Purcell–Meiboom–Gill (CPMG) sequence⁹ this is achieved by a 90° shift between the phase of the π pulses and the phase of the preparation pulse. Other compensated sequences, which have been proposed¹⁰ with a similar aim, involve cycles for 4, 8, or 16 π pulses.

3.2 Transient Nutations

A different approach is needed in order to examine the applicability of transient nutation as a tool for dipolar spectroscopy. This approach permits, at the same time, an evaluation of the effect of π pulses of finite width on dipolar spectra obtained using the CPMG sequence. In the laboratory frame, the total Hamiltonian $\hat{\mathcal{H}}$ includes, in addition to the Zeeman interaction $\hat{\mathcal{H}}_Z$, an interaction with a time-dependent rf field at resonance which may be amplitude modulated by pulses. It also includes a distribution of shifts [equation (7)] and the secular homonuclear dipole–dipole couplings $\hat{\mathcal{H}}_d$:

$$\hat{\mathcal{H}} = -\hbar\omega_0\hat{I}_z - 2\hbar\omega_1(t)\hat{I}_x \cos \omega_0 t - 2t\omega_1(t)I_x \cos \omega_0 t + \sum_i \Delta\sigma_i \hat{I}_{zi} + \hat{\mathcal{H}}_d \quad (8)$$

where, from equations (1) and (2),

$$\hat{\mathcal{H}}_d = \sum_{i,j} A_{ij} (\hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j - 3\hat{I}_{zi}\hat{I}_{zj}) \quad (9)$$

In the transient nutation experiment, an oscillating rf field of constant amplitude $2\omega_1/\gamma$ is applied suddenly along the x axis of the laboratory frame starting from equilibrium. The ensuing transient precession about the effective field in the rotating frame is then recorded, either point by point after an rf field of variable duration or by sampling through appropriately chosen receiver windows, and Fourier transformed. For simplicity, the conditions for decoupling of the nonresonant spins are assumed to hold, and consequently heteronuclear dipolar interactions have not been included in $\hat{\mathcal{H}}$.

One is interested in the evolution of the density operator $\hat{\rho}'$, in a rotating tilted frame,¹¹ where one of the two rotating components of the oscillating magnetic field is stationary along the z axis. The transformed density operator $\hat{\rho}'$ can be obtained from the laboratory frame operator $\hat{\rho}$ through the transformation $\hat{\rho}' = \hat{P}\hat{R}\hat{\rho}\hat{R}^{-1}\hat{P}^{-1}$ where

$$\hat{P} = \exp(i\pi\hat{I}_y/2); \quad \hat{R} = \exp(i\omega_0 t \hat{I}_z) \quad (10)$$

Starting from the time evolution of the density operator in the laboratory frame, the evolution of $\hat{\rho}'$ can be shown¹¹ to be governed by an effective Hamiltonian

$$\hat{\mathcal{H}}'_e = \hat{P}\hat{R}\hat{\mathcal{H}}_e\hat{R}^{-1}\hat{P}^{-1} \quad (11)$$

where $\hat{\mathcal{H}}_e = \hat{\mathcal{H}} - \hat{\mathcal{H}}_Z$, and $\hat{\mathcal{H}}_Z = -\hbar\omega_0\hat{I}_z$ denotes the Zeeman interaction.

Since the secular interactions in $\hat{\mathcal{H}}$ [equations (8) and (9)] commute with $\hat{R}$, the calculation of $\hat{\mathcal{H}}'_e$ from equations (10) and (11) is simplified. Neglecting terms oscillating at frequency $2\omega_0$, the effective Hamiltonian in the rotating tilted frame reduces to

$$\begin{aligned} \hat{\mathcal{H}}'_e = & -\hbar\omega_1\hat{I}_z + \sum_{i,j} A_{ij} (\hat{\mathbf{I}}_i \cdot \hat{\mathbf{I}}_j - 3\hat{I}_{xi}\hat{I}_{xj}) \\ & - \sum_i \Delta\sigma_i \hat{I}_{xi} \end{aligned} \quad (12)$$

Furthermore, if the amplitude of the rotating magnetic field ω_1/γ is large compared to the strength of the internal fields, and the system is initially in a state described by an equilibrium density operator $\hat{\rho}(0) = \text{const} \times \hat{I}_z$ in the laboratory frame [and hence by $\hat{\rho}'(0) = -\text{const} \times \hat{I}_x$ in the rotating tilted frame], the decay of the transient nutation signal is governed by the terms in equation (13) which commute with $\hat{I}_z$. It is therefore convenient to write, with the help of raising and lowering operators, the last two terms in equation (12) as a purely secular part, obeying the selection rule⁴ $\Delta(m_i + m_j) = 0$, plus nonsecular terms satisfying $\Delta(m_i + m_j) \neq 0$. This leads to:

$$\begin{aligned} \hat{\mathcal{H}}'_e = & -\hbar\omega_1\hat{I}_z - \frac{1}{2}\hat{\mathcal{H}}_d - \frac{3}{4} \sum_{i,j} A_{ij} (\hat{I}_{i+}\hat{I}_{j+} + \hat{I}_{i-}\hat{I}_{j-}) \\ & - \frac{1}{2} \sum_i \Delta\sigma_i (\hat{I}_{i+} + \hat{I}_{i-}) \end{aligned} \quad (13)$$

Equation (13) shows that the transient nutation signal satisfies the requirements for dipolar spectroscopy. Since the last two terms have become nonsecular and do not contribute to the decay, inhomogeneous broadening caused by resonance shifts is suppressed, although an inhomogeneous rf field may still cause broadening.¹² In addition, the strength of the secular dipolar term in equation (14) is one-half the value of the dipolar interaction in the laboratory frame¹³ [equation (9)]. Hence the width of the spectrum of isolated pairs shown in Figure 1 is expected to be half the value calculated from equation (3).

3.3 CPMG Sequence with Finite Pulse Widths

The system is prepared by an initial $\pi/2$ pulse and evolves during a time interval τ . A train of π pulses of width t_w , separated by intervals 2τ , and phase shifted by 90° with respect to the initial $\pi/2$ pulse is then applied. The signal amplitudes at the echo maxima are further recorded as a function of time, and Fourier transformed to obtain the frequency spectrum.

Since for the CPMG case, $\omega_1(t)$ in equation (8) represents a periodic function of period $T = 2\tau + t_w$ consisting of rectangular pulses with amplitudes $\omega_{1a} = \pi/t_w$, the steps leading from equation (8) to equation (13) yield an effective Hamiltonian identical to $\hat{\mathcal{H}}'_e$ [equation (13)], but with a time-dependent term $\hbar\omega_1(t)\hat{I}_z$. Moreover, since one is observing the evolution stroboscopically, it is convenient to transform $\hat{\mathcal{H}}'_e$ to a ‘toggling frame’ where the precession about externally

applied fields, either static or time-dependent, is removed. This is achieved by the transformation¹¹

$$\hat{\rho}'_{\text{et}}(t) = \exp[-i\phi(t)\hat{I}_z/2] \hat{\rho}'_{\text{e}}(t) \exp[i\phi(t)\hat{I}_z/2] \quad (14)$$

where:

$$\phi(t) = 2 \int_0^t \omega_1(t') dt' \quad (15)$$

The evolution of $\hat{\rho}'_{\text{et}}(t)$, given by equations (14) and (15), is governed by the effective Hamiltonian

$$\begin{aligned} \hat{\mathcal{H}}'_{\text{et}} = & -\frac{1}{2}\hat{\mathcal{H}}_{\text{d}} - \frac{3}{4} \sum_{i,j} A_{ij} \{ \hat{I}_{i+} \hat{I}_{j+} \exp[i\phi(t)] + \text{c.c.} \} \\ & - \frac{1}{2} \sum_i \Delta \sigma_i \{ \hat{I}_{i+} \exp[-i\phi(t)/2] + \text{c.c.} \} \end{aligned} \quad (16)$$

where c.c. denotes the Hermitian conjugate of the operators within the braces.

As pointed out by Waugh and Wang,¹¹ only the zero-frequency components of the time-dependent terms in equation (16) can contribute to the observed decay, because the time-dependent parts correspond to frequencies much higher than A_{ij} and $\Delta \sigma_i$ if $1/(t_w + 2\tau)$ is sufficiently large. For the periodic functions in equation (16), which involve sine and cosine functions of $\phi(t)$ and $\phi(t)/2$, the zero-frequency components can be obtained graphically in a relatively simple manner by calculating the corresponding averages over one period. Assuming the first π pulse at time from τ from the origin and a sequence of perfect rectangular π pulses of width t_w , the zero-frequency component of $\exp[\pm i\phi(t)/2]$ can be seen to vanish leading to a suppression of shifts in equation (16). On the other hand, the dc component of $\exp[i\phi(t)]$, denoted by $\mathcal{L}$, is given by³

$$\mathcal{L} = \frac{1}{T} \int_0^T \cos \phi(t') dt' = 1 - D \quad (17)$$

where $T = 2\tau + t_w$ is the period, and $D = 2\tau/T$ denotes the duty factor of the sequence of π pulses.

In order to evaluate the effect of π pulses of finite width upon the spectrum of isolated pairs (Figure 1), one can diagonalize the static part of $\hat{\mathcal{H}}'_{\text{et}}$ [equation (16)] given by

$$\begin{aligned} \hat{\mathcal{H}}'_{\text{et}} = & -\frac{1}{2}A_{12}(\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 - 3\hat{I}_{z1}\hat{I}_{z2}) - \frac{3}{4}A_{12}(\hat{I}_{1+}\hat{I}_{2+} + \hat{I}_{1-}\hat{I}_{2-}) \\ & + \hat{I}_{1-}\hat{I}_{2-}\mathcal{L}^* \end{aligned} \quad (18)$$

For spin- $\frac{1}{2}$ nuclei, an adequate basis is composed of the singlet and triplet states introduced earlier in connection with equations (1) and (2). The states $|t_0\rangle$ and $|s_0\rangle$ are still eigenfunctions of $\hat{\mathcal{H}}'_{\text{et}}$, whereas two appropriate linear combinations of $|t_+\rangle$ and $|t_-\rangle$ constitute the other two eigenstates.

The quantity of interest in the CPMG experiment is proportional to $\text{Tr}(\hat{\rho}'_{\text{et}}(t)\hat{I}_z)$ and can be explicitly computed³ from the known eigenvalues and eigenvectors yielding a spectrum of two lines for a given orientation of $\mathbf{B}_0$. The frequency separation Δ between the lines for $\theta_{12} = \pi/2$, corresponding to the singularities in the spectrum of randomly oriented pairs

(Figure 1) is governed by the second term in equation (18), since the first term commutes with $\hat{\rho}'_{\text{et}}(0) = \text{const} \times \hat{I}_z$ and does not cause any decay. It can be shown³ that Δ is given by

$$\Delta = 3\gamma^2\hbar(1 - D)/4\pi r_{12}^3 \quad (19)$$

4 DIPOLAR SPECTRA

Figure 2 shows a ^{13}C spectrum of polycrystalline acetic acid at $T = 80\text{ K}$; there is a very close correspondence with the theoretical spectrum shown in Figure 1. The sample contains 4% doubly ^{13}C -labeled acetic acid dissolved in ^{13}C -depleted acetic acid. A modified CPMG sequence with $2\tau = 86.4\ \mu\text{s}$ and $t_w = 9.6\ \mu\text{s}$, including proton decoupling and cross polarization,¹⁴ was employed. A central peak partially caused by spin locking⁷ in the average rf field is omitted for clarity.

Dipolar spectra obtained by employing transient nutations generally display poorer resolution than do those obtained with CPMG sequences, because of the reduction in spectral range by a factor of 2 [equation (13)]. Good resolution is especially important when pairs with more than one interatomic distance are involved.¹⁵ On the other hand, for the CPMG sequence, the splitting Δ (Figure 2) depends on the duty factor, but

Figure 2 ^{13}C spectrum of polycrystalline acetic acid at $T = 80\text{ K}$. The sample contains 4% doubly ^{13}C -labeled acetic acid dissolved in ^{13}C -depleted acetic acid. A modified CPMG sequence with pulse separation $2\tau = 86.4\ \mu\text{s}$ and pulse width $t_w = 9.6\ \mu\text{s}$ was employed (Reproduced by permission from M. Engelsberg and C. S. Yannoni, *J. Magn. Reson.*, 1990, **88**, 393)

Figure 3 ^{13}C dipolar spectra of benzene ($1,2\text{-}^{13}\text{C}_2$) chemisorbed on $\text{Pt}/\eta\text{-Al}_2\text{O}_3$ obtained by a modified CPMG sequence at various temperatures. The narrow central peak, partially due to spin locking, has been omitted for clarity in all spectra, except the one at 125 K. (Inset) Conventional (FT of FID) proton-decoupled spectrum in the same system at $T = 80\text{ K}$, with shifts measured with respect to a TMS reference (Reproduced by permission from M. Engelsberg, C. S. Yannoni, M. A. Jacintha, C. Dybowski, and R. E. de Souza, *J. Phys. Chem.*, 1994, **98**, 2397. © 1994 American Chemical Society)

the variation has been shown experimentally³ to agree with the linear dependence predicted by equation (19). Thus a simple correction permits accurate measurement of interatomic distances.³

One example of dipolar spectroscopy which helps to illustrate its applicability is provided by the study of benzene chemisorbed on an η -alumina-supported platinum catalyst.⁶ The inset in Figure 3 shows a conventional proton-decoupled ^{13}C spectrum of benzene ($\nu_0 = 15\text{ MHz}$), doubly labeled in *ortho* positions, chemisorbed on $\text{Pt}/\eta\text{-Al}_2\text{O}_3$ at $T = 80\text{ K}$, obtained by FT of the FID. Also shown in Figure 3 are spectra of the same system at various temperatures obtained from a modified CPMG sequence, where the suppression of inhomogeneous broadening uncovers a rich variety of geometrical and dynamical information. The four peaks at the lowest temperature correspond to benzene molecules at different sites, not to different bond lengths.^{6,16} For some sites

the molecules are rapidly reorienting about the hexad axis,¹⁷ corresponding to $\psi_{12} = \pi/2$ in equation (4), while for others this reorientation rate is small. This explains the difference of a factor of 2 in the splittings of the two inner peaks compared with the outer peaks. At temperatures above 80 K, the spectra can be simulated⁶ assuming that the axis of hindered rotation no longer remains perpendicular to the plane of the molecule.

Other examples^{15,18,19} of dipolar spectra in a variety of systems further illustrate the usefulness of the techniques described in Section 3 for probing the structure and dynamics of solids.

1 INTRODUCTION

Double rotation (DOR) is a technique of fast sample rotation. It was designed primarily for obtaining high-resolution NMR spectra of half-integer quadrupolar nuclei in solids along with the technique of dynamic angle spinning (DAS).^{1–3} This article describes briefly the theory and the experimental implementation of DOR.

One of the major problems of NMR spectroscopy in solids is its inferior resolution compared to that in liquids. In a powder or polycrystalline sample the random distribution of crystallite orientations with respect to the external magnetic field often causes line broadening through the angular dependence of spin interactions including the chemical shift anisotropy (CSA). In addition, line broadening may also arise from spin–spin interactions even in a single crystal. As a result, resonance lines associated with crystallographically inequivalent sites often overlap with each other, resulting in a loss of important structural information. In contrast, NMR spectra in liquids are of high resolution. Since molecules in liquids experience a rapid isotropic tumbling, only the scalar part of spin interactions such as the isotropic chemical shift is recorded in an NMR spectrum. The angular dependence, for instance, is averaged out by rapid molecular tumbling at a rate much faster than the timescale of the involved spin interactions. It is intriguing, as demonstrated by the magic angle spinning (MAS) technique^{4,5} which rotates the entire sample rapidly along a single axis inclined at 54.74° with respect to the external magnetic field, that a uniform sample motion can accomplish line-narrowing effects in solids that are similar to the effects of rapid isotropic molecular tumbling in liquids. The reason for this ‘magic’ effect is based on the symmetry of the spin interactions.⁶

MAS is very effective in removing broadening mechanisms such as CSA and dipole–dipole interactions.^{4,5,7,8} High-resolution MAS spectra of various nuclei, including ^{13}C , ^{29}Si , ^{31}P , and ^1H , provide valuable information in the study of solid materials. It turns out that the ‘magic’ of MAS is much less effective for half-integer quadrupolar nuclei such as ^{27}Al , ^{17}O , ^{11}B , and ^{23}Na . In general, quadrupole interactions are very strong in solids with a noncubic local environment. Typically the line broadening generated by the angular dependence of quadrupole interactions in a strong static external magnetic field is large compared with shielding anisotropies. In general,

only the $\frac{1}{2} \leftrightarrow -\frac{1}{2}$ central transition can be readily observed because the central transition is broadened only by the second-order perturbation of quadrupole interactions to the Zeeman interaction. In many solids, even this second-order effect of quadrupole interactions contributes significantly to the line broadening. This has been a major obstacle for solid state NMR of half-integer quadrupolar nuclei in various materials, including molecular sieves, zeolites, and minerals. Since the angular dependence of the second-order quadrupole interaction has a different symmetry than the first-order effect,⁶ it is not surprising that the simple trajectory of MAS cannot replace the motion of isotropic tumbling. Figure 1(a) shows the static spectrum of the spin $I = \frac{3}{2}$ nucleus ^{23}Na in a sample containing a mixture of sodium sulfate and sodium oxalate with a molar ratio of 2:1. All spectra shown here were recorded on 400 MHz NMR spectrometers. Both sodium sulfate and sodium oxalate contain a single sodium site. The two inequivalent sodium sites are obviously not resolved in the static spectrum. Under MAS the linewidth is reduced somewhat, as shown in Figure 1(b). The resolution, however, is still too low to distinguish unambiguously the two inequivalent sodium sites. One may think that isotropic tumbling is the only solution for removing the broadening due to the second-order quadrupole interactions. Fortunately, this is not the case. Solutions employing simple mechanical motions exist, including DOR and DAS.

In a DOR NMR experiment the sample is spun rapidly inside a sample-containing small inner rotor which is embedded inside a large outer rotor.^{9,10} Under the DOR condition the inner rotor spins along an axis which is inclined at an angle $\beta_1 = 30.56^\circ$ with respect to the spinning axis of the outer rotor; simultaneously, the outer rotor spins along an axis which is set at an angle $\beta_2 = 54.74^\circ$ with respect to the external magnetic field B_0 . This is illustrated in Figure 2(a). The effect of DOR is demonstrated clearly in Figure 1(c) with the inner rotor spinning at about 5 kHz and the outer rotor spinning at 970 Hz. The two inequivalent sodium sites in the mixture of sodium sulfate and sodium oxalate are completely resolved under DOR with a residual linewidth of 80 Hz. In addition to the two centerbands, which are expanded in Figure 1(d), the DOR spectrum also contains spinning sidebands because of the limited spinning speeds of the inner and outer rotors. The intensity ratio of the two components in Figure 1(c) agrees with the 2:1 molar ratio of the sodium sulfate versus sodium oxalate in this mixture.

2 AVERAGING OF THE QUADRUPOLE INTERACTION UNDER DOR

2.1 The Trajectory of DOR

In order to understand the time dependence of the Hamiltonian under DOR, the motion of the sample has to be described precisely. This is accomplished through three sets of Euler angles relating the orientation of the external magnetic field B_0 to a coordinate frame associated with a crystallite. The first set of Euler angles $(0, \beta_2, \omega_R t)$ corresponds to a rotation which rotates the laboratory (LAB) coordinate frame (X, Y, Z) into coincidence with the coordinate frame

Figure 1 NMR spectra of ^{23}Na central transition in a 2:1 polycrystalline mixture of sodium sulfate and sodium oxalate. (a) Static spectrum, and (b) MAS spectrum with a rotor spinning speed of 5.7 kHz. (c) DOR spectrum with the outer rotor spinning at 970 Hz clearly revealing the two-line structure. (d) An expanded version of (c) showing the centerband peaks originating from the two components of the mixture

(x_2, y_2, z_2) associated with the outer rotor. The Z and z_2 axes are along the external static magnetic field $\mathbf{B}_0$ and the spinning axis of the outer rotor, respectively, and ω_R is the angular velocity of the outer rotor. Here, both the first and the third Euler angles can be chosen as zero at time $t = 0$ because both the orientations of the (X, Y) and the (x_2, y_2) axes can be defined arbitrarily at time $t = 0$. The angle β_2 is the angle between the external static magnetic field $\mathbf{B}_0$ and the spinning axis of the outer rotor. As explained later, the exact value of β_2 , which can be set experimentally, is crucial. The second set of Euler angles $(\alpha_1, \beta_1, \omega_r t)$ describes a rotation

Figure 2 (a) The basic elements of a DOR NMR probe. The spinning axis of the outer rotor is at an angle of 54.74° with respect to $\mathbf{B}_0$, and the spinning axis of the inner rotor is set at an angle of 30.56° with respect to the outer rotor axis. By adjusting the ratio of moments of inertia $I_{y''}/I_{z''}$, the addition of the two vector components of the angular momentum along the inner rotor axis z'' and the y'' axis can be made to point along the outer rotor axis z_2 , so that spinning the outer rotor will not affect the orientation of the total angular momentum of the inner rotor. (b) Illustration of the $\alpha_1 = 0$ and $\alpha_1 = 180^\circ$ positions

which rotates the outer rotor coordinate frame (x_2, y_2, z_2) into coincidence with the coordinate frame (x_1, y_1, z_1) associated with the inner rotor. The z_1 axis is along the spinning axis of the inner rotor and ω_r is the angular velocity of the inner rotor. Note that the angle α_1 cannot be set arbitrarily to zero because the only remaining degree of freedom, namely the choice of the orientations of the (x_1, y_1) axes, has been used to set the third Euler angle $\omega_r t$ to be zero at time $t = 0$. When $\alpha_1 = 0$ or 180° , the inner rotor axis at $t = 0$ is in the plane defined by the spinning axis of the outer rotor and the magnetic field $\mathbf{B}_0$, as shown in Figure 2(b). The angle α_1 is an operationally well-defined angle which can be correlated with the timing of the rf excitation pulse through synchronization by an optical sensor. The third set of Euler angles $(\alpha^i, \beta^i, \gamma^i)$ describes a rotation which rotates the coordinate frame (x_1, y_1, z_1) into coincidence with the coordinate frame (x^i, y^i, z^i) which is associated with a particular crystallite of the sample.

2.2 The Quadrupole Interaction

The Hamiltonian of the quadrupole interaction can be expressed as^{7,8,11}

$$\hat{\mathcal{H}}_Q = \frac{eQq_{zz}}{2I(2I-1)} \sum_{m=-2}^2 (-1)^m V^{(2,-m)} \hat{T}^{(2,m)} \quad (1)$$

where e is the electronic charge, Q is the quadrupole moment of the nucleus, I is the spin quantum number, q_{zz} is one of the principal components ($|q_{zz}| \geq |q_{yy}| \geq |q_{xx}|$) of the Cartesian electric-field-gradient (EFG) tensor in the principal axis system (PAS), and $\hat{T}^{(2,m)}$ and $V^{(2,m)}$ are irreducible second-rank tensors. $T^{(2,m)}$ are spin operators given by

$$\left. \begin{aligned} \hat{T}^{(2,0)} &= \frac{1}{\sqrt{6}}(3\hat{I}_z^2 - \hat{I}^2), \\ \hat{T}^{(2,\pm 1)} &= \frac{1}{\sqrt{2}}(\hat{I}_{\pm 1}\hat{I}_z + \hat{I}_z\hat{I}_{\pm 1}), \hat{T}^{(2,\pm 2)} = \hat{I}_{\pm 1}^2 \end{aligned} \right\} \quad (2)$$

where $\hat{I}_{\pm 1} = \mp(\hat{I}_x \pm i\hat{I}_y)/\sqrt{2}$, and $\hat{I}_x$, $\hat{I}_y$, and $\hat{I}_z$ are components of the spin angular momentum operator $\hat{\mathbf{I}}$. $V^{(2,m)}$, which relate only to spatial parameters, can be expressed as¹²

$$V^{(2,m)} = \sum_{m'=-2}^2 D_{m',m}^{(2)}(\alpha, \beta, \gamma) \rho^{(2,m')} \quad (3)$$

where $D_{m',m}^{(2)}$ are the Wigner rotation matrices, (α, β, γ) are Euler angles describing a rotation which brings the PAS frame of the EFG tensor into coincidence with the LAB frame, and $\rho^{(2,m')}$ are components of the reduced EFG tensor (the EFG tensor scaled by $1/q_{zz}$) in the PAS of the EFG tensor, given by

$$\rho^{(2,0)} = \sqrt{\frac{3}{2}}, \quad \rho^{(2,\pm 1)} = 0, \quad \rho^{(2,\pm 2)} = \frac{1}{2}\eta \quad (4)$$

where η is the asymmetry parameter of the EFG tensor, defined as $\eta = (q_{xx} - q_{yy})/q_{zz}$. Notice that the angles (β, α) are in fact the polar angles of the orientation of the external static magnetic field $\mathbf{B}_0$ with respect to the PAS of the EFG tensor.

For NMR experiments in a high external magnetic field the Zeeman interaction $\hat{\mathcal{H}}_Z$ dominates, and the quadrupole interaction $\hat{\mathcal{H}}_Q$ can be treated as a perturbation. Since the Zeeman eigenstates $|m\rangle = |-I\rangle, \dots, |I\rangle$ are nondegenerate, perturbation calculations can be carried out easily. The first-order perturbation is given by

$$\Delta E_m^{(1)} = \langle m | \hat{\mathcal{H}}_Q | m \rangle = \frac{[3m^2 - I(I+1)]h\chi}{2\sqrt{6}I(I-1)} V^{2,0} \quad (5)$$

where $\chi = eq_{zz}Q/h \equiv e^2qQ/h$ is the nuclear quadrupole constant and h is the Planck constant. It is evident from equation (3) that $V^{(2,0)}$ depends on the orientation of the crystallite. Thus, the effect of this first-order perturbation will cause line broadening in a powder sample. It is clear, however, that the resonance frequency of the central transition $\nu(\frac{1}{2} \leftrightarrow -\frac{1}{2}) = \nu_L + (\Delta E_{-1/2}^{(1)} - \Delta E_{1/2}^{(1)})/h = \nu_L$, where ν_L represents the Larmor frequency, is not affected by the quadrupole interaction to the first order. This is the reason why the resonance of the $\frac{1}{2} \leftrightarrow -\frac{1}{2}$ central transition is much narrower than the resonances of the satellite transitions such as the $\frac{3}{2} \leftrightarrow \frac{1}{2}$ transition.

The effect of the quadrupole interaction on the $\frac{1}{2} \leftrightarrow -\frac{1}{2}$ central transition has to be evaluated by the second-order perturbation, which is given by

$$\Delta E_m^{(2)} = \sum_{\substack{m'=-I \\ m' \neq m}}^I \frac{|\langle m | \hat{\mathcal{H}}_Q | m' \rangle|^2}{E_m^{(0)} - E_{m'}^{(0)}} \quad (6)$$

where $E_m^{(0)}$ is the unperturbed energy eigenvalue of the Zeeman eigenstate $|m\rangle$. This second-order perturbation of the quadrupole interaction can be evaluated easily using equations (1) and (6). The resulting resonance frequency shift $\Delta\nu(\frac{1}{2} \leftrightarrow -\frac{1}{2}) = (\Delta E_{-1/2}^{(2)} - \Delta E_{1/2}^{(2)})/h$ for the central transition can be expressed as

$$\Delta\nu(\frac{1}{2} \leftrightarrow -\frac{1}{2}) = \frac{-\chi^2}{[2I(2I-1)]^2\nu_L} \times [I(I+1) - \frac{3}{4}][2|V^{(2,1)}|^2 - |V^{(2,2)}|^2] \quad (7)$$

using the fact that $|V^{(2,2)}|^2 = |V^{(2,-2)}|^2$, $|V^{(2,1)}|^2 = |V^{(2,-1)}|^2$, and the properties of the spin operators. The term $|V^{(2,2)}|^2$ can be written as

$$|V^{(2,2)}|^2 = \sum_{m,m'=-2,0,2} D_{m',2}^{(2)}(\alpha, \beta, \gamma) D_{m,2}^{*(2)}(\alpha, \beta, \gamma) \rho^{(2,m')} \rho^{(2,m)} \quad (8)$$

Terms with m or $m' = \pm 1$ vanish in equation (8) because $\rho^{(2,\pm 1)} = 0$. From the property $D_{m,m'}^{*(2)} = (-1)^{m-m'} D_{-m,-m'}^{(2)}$ for even m and m' , equation (8) can be modified as

$$|V^{(2,2)}|^2 = \sum_{m,m'=-2,0,2} D_{m',2}^{(2)}(\alpha, \beta, \gamma) D_{-m,-2}^{(2)}(\alpha, \beta, \gamma) \times \rho^{(2,m')} \rho^{(2,m)} \quad (9)$$

According to the coupling rule,¹² the product $D_{m',2}^{(2)} D_{-m,-2}^{(2)}$ can be expressed as

$$D_{m',2}^{(2)} D_{-m,-2}^{(2)} = \sum_{l=0}^4 c(2\ 2\ l; m' - m) c(2\ 2\ l; 2 - 2) D_{m'-m,0}^{(l)} \quad (10)$$

where $c(l_1\ l_2\ l; m_1\ m_2)$ are the Clebsch–Gordan coefficients. In fact, only terms with $l = 0, 2, 4$ in equation (10) will contribute in equation (9) because¹² $c(l_1\ l_2\ l; m_1\ m_2) = (-1)^{l_1+l_2+l} c(l_2\ l_1\ l; m_2\ m_1)$ and $l_1 = l_2 = 2$ will make $l = 1$ and $l = 3$ terms disappear from equation (9). Similarly, it can be shown that

$$|V^{(2,1)}|^2 = - \sum_{m,m'=-2,0,2} D_{m',1}^{(2)}(\alpha, \beta, \gamma) D_{-m,-1}^{(2)}(\alpha, \beta, \gamma) \times \rho^{(2,m')} \rho^{(2,m)} \quad (11)$$

where the product $D_{m',1}^{(2)} D_{-m,-1}^{(2)}$ can be expressed as

$$D_{m',1}^{(2)} D_{-m,-1}^{(2)} = \sum_{l=0,2,4} c(2\ 2\ l; m' - m) \times c(2\ 2\ l; 1 - 1) D_{m'-m,0}^{(l)} \quad (12)$$

Table 1 Values of the Coefficient $a_{l,m}$ for Different l and m

	$m = 0$	$m = \pm 2$	$m = \pm 4$
$l = 0$	$-\frac{3}{10} \left(1 + \frac{\eta^2}{3}\right)$		
$l = 2$	$-\frac{6}{7} \left(1 - \frac{\eta^2}{3}\right)$	$\frac{2\sqrt{6}}{7} \eta$	
$l = 4$	$\frac{81}{70} \left(1 + \frac{\eta^2}{18}\right)$	$\frac{27}{14\sqrt{10}} \eta$	$\frac{9}{4\sqrt{70}} \eta^2$

The matrices $D_{m'-m,0}^{(l)}(\alpha, \beta, \gamma)$ in equations (10) and (12) are related to the spherical harmonics as¹²

$$\begin{aligned} D_{m'-m,0}^{(l)}(\alpha, \beta, \gamma) &= \sqrt{\frac{4\pi}{2l+1}} Y_{l,m'-m}^*(\beta, \alpha) \\ &= \sqrt{\frac{4\pi}{2l+1}} (-1)^{m'-m} Y_{l,m-m'}(\beta, \alpha) \end{aligned} \quad (13)$$

Thus, the resonance frequency shift $\Delta\nu(\frac{1}{2} \leftrightarrow -\frac{1}{2})$ caused by the second-order effect of the quadrupole interaction can be expressed as a linear combination of spherical harmonics,²

$$\begin{aligned} \Delta\nu(\frac{1}{2} \leftrightarrow -\frac{1}{2}) &= \frac{\chi^2}{[2I(2I-1)]^2 \nu_L} \left(I(I+1) - \frac{3}{4} \right) \\ &\times \sum_{l=0,2,4} \sum_{\substack{m=-l \\ \text{even}}}^l a_{l,m} \sqrt{\frac{4\pi}{2l+1}} Y_{l,m}(\beta, \alpha) \end{aligned} \quad (14)$$

where the coefficients $a_{l,m}$ are listed in Table 1. The line broadening comes from the fact that the orientation (β, α) associated with each crystallite distributes randomly in a powder sample. Since $Y_{0,0}(\beta, \alpha) = 1/\sqrt{4\pi}$, the $l = 0$ term in equation (14) contributes to $\Delta\nu(\frac{1}{2} \leftrightarrow -\frac{1}{2})$ a quantity

$$\Delta\nu_{\text{iso}}^{(2)} = -\frac{3}{10} \frac{\chi^2 [I(I+1) - \frac{3}{4}]}{\nu_L [2I(2I-1)]^2} (1 + \frac{1}{3}\eta^2) \quad (15)$$

which is independent of the polar angles (β, α) . $\Delta\nu_{\text{iso}}^{(2)}$ is called the isotropic second-order quadrupolar shift. This isotropic shift always exists even under sample spinning or the tumbling motion unless the rate of motion is much faster than the Larmor frequency.

2.3 The Effect of DOR

The sample motion under DOR renders the Hamiltonian time-dependent through the changes of the polar angles (β, α) of the external magnetic field with respect to the PAS system of the EFG tensor. Since the adjacent energy levels (nondegenerate) under the static condition are separated from each other approximately by $h\nu_L$, and the quadrupole interaction only adds a small correction, the time dependence of the Hamiltonian under DOR can be considered to be adiabatic given that the spinning rates (typically a few kilohertz) of the double rotor are much smaller than ν_L . This

time dependence can be incorporated in $\Delta\nu(\frac{1}{2} \leftrightarrow -\frac{1}{2})$ through the following transformation of the spherical harmonics:¹²

$$Y_{l,m}(\Theta, \Phi) = \sum_{m'=-l}^l Y_{l,m'}(\theta, \phi) D_{m',m}^{(l)}(\alpha', \beta', \gamma') \quad (16)$$

where (θ, ϕ) are the polar angles of a vector in the old coordinate frame, (Θ, Φ) are the polar angles of the same vector in the new coordinate frame, and $(\alpha', \beta', \gamma')$ are the Euler angles of a rotation which brings the old coordinate frame into coincidence with the new coordinate frame. Applying this transformation three times, LAB $\rightarrow$ outer rotor $\rightarrow$ inner rotor $\rightarrow$ PAS, the spherical harmonics $Y_{l,m}(\beta, \alpha)$ in equation (14) can be expressed as

$$\begin{aligned} Y_{l,m}(\beta, \alpha) &= \sum_{m',m'',n=-l}^l D_{m',m}^{(l)}(\alpha^i, \beta^i, \gamma^i) D_{m'',m'}^{(l)}(\alpha_1, \beta_1, \omega_R t) \\ &\times D_{n,m''}^{(l)}(0, \beta_2, \omega_R t) Y_{l,n}(0, 0) \end{aligned} \quad (17)$$

The factors $D_{m',m}^{(l)}(\alpha^i, \beta^i, \gamma^i)$ cause line broadening because of the random distribution of the Euler angles $(\alpha^i, \beta^i, \gamma^i)$ in a powder sample.

Since $Y_{l,n}(0,0)=0$ for $n \neq 0$ and $Y_{l,0}(0, 0) = \sqrt{(2l+1)/4\pi}$, equation (17) can be reduced to

$$\begin{aligned} Y_{l,m}(\beta, \alpha) &= \sum_{m',m''=-l}^l \sqrt{\frac{(2l+1)}{4\pi}} \\ &\times D_{m',m}^{(l)}(\alpha^i, \beta^i, \gamma^i) d_{m'',m'}^{(l)}(\beta_1) d_{0,m''}^{(l)}(\beta_2) \\ &\times \exp[-i(m'\omega_R + m''\omega_R)t] \exp(-im''\alpha_1) \end{aligned} \quad (18)$$

where $d_{m',m}^{(l)}$ are the reduced Wigner rotation matrices. Assuming that $m'\omega_R + m''\omega_R \neq 0$ for all pairs of m' and m'' in equation (18) unless $m' = m'' = 0$, for instance by choosing $\omega_R > 5\omega_R$, then the only term remaining in equation (18) after time averaging is (the secular term)

$$Y_{l,m}(\beta, \alpha) = \sqrt{\frac{(2l+1)}{4\pi}} D_{0,m}^{(l)}(\alpha^i, \beta^i, \gamma^i) d_{0,0}^{(l)}(\beta_1) d_{0,0}^{(l)}(\beta_2) \quad (19)$$

This term depends on the angles β^i and γ^i . For $l = 2$ and $l = 4$ this anisotropic effect can be completely eliminated by choosing the angles β_1 and β_2 such that both

$$d_{0,0}^{(2)}(\beta_1) d_{0,0}^{(2)}(\beta_2) = P_2(\cos \beta_1) P_2(\cos \beta_2) = 0 \quad (20a)$$

and

$$d_{0,0}^{(4)}(\beta_1) d_{0,0}^{(4)}(\beta_2) = P_4(\cos \beta_1) P_4(\cos \beta_2) = 0 \quad (20b)$$

where $P_2(\cos \varphi) \equiv (3 \cos^2 \varphi - 1)/2$ and $P_4(\cos \varphi) \equiv (35 \cos^4 \varphi - 30 \cos^2 \varphi + 3)/8$ are the second and fourth Legendre polynomials. The solutions for equations (20a) and (20b) are $\beta_1 = 54.74^\circ$ and $\beta_2 = 30.56^\circ$ or $\beta_1 = 54.74^\circ$ and $\beta_2 = 70.12^\circ$.

Figure 3 NMR spectra of ^{17}O central transition in polycrystalline CaSiO_3 wollastonite. (a) Static spectrum, and (b) MAS spectrum with a rotor speed of 5.6 kHz. (c) DOR spectrum with outer rotor spinning at 830 Hz. Lines arising from eight resolved oxygen sites are indicated by arrows; other peaks are spinning sidebands. The chemical shift reference is ^{17}O in water

Dramatic effects of line narrowing by DOR have been demonstrated for many half-integer quadrupolar nuclei. For instance, the ^{17}O spectrum of the mineral wollastonite can be improved significantly by DOR. Figure 3(a) and (b) show the static and MAS ^{17}O spectra of wollastonite, respectively. Clearly, the nine crystallographically distinct sites in wollastonite are far from being resolved under MAS. The resolution is enhanced substantially under DOR, as shown in Figure 3(c) where eight resonance peaks can be clearly identified. Peaks which are not indicated by arrows in Figure 3(c) are spinning sidebands. In order to obtain a clean spectrum with minimal sideband intensity, fast spinning speeds of the inner and outer rotors are required.

3 PRINCIPLES OF THE DOR PROBE DESIGN

The basic elements of a DOR probe^{9,10} are illustrated in Figure 2. The large outer rotor is set at the magic angle of 54.74° with respect to the static magnetic field. The rf coil is wound around the outer rotor. The air bearing and drive

system for the outer rotor is similar to the conventional MAS system as shown in Figure 4(a). The outer rotor, represented by the shaded area in Figure 4(a), is centered by two pins (part 9), supported by the air bearing (part 6), and driven by air jets (part 7). As expected, the internal structure of the outer rotor is far more complicated than a regular MAS spinner. As shown in Figure 4(b), it contains the entire air bearing and drive system for the inner rotor which spins along an axis set at an angle of 30.56° with respect to the outer rotor axis. The inner rotor (part 1) is also centered by two pins (part 5) mounted on two small caps (part 15). The air bearing (part 3) and drive (part 4) for the inner rotor are mounted inside the body of the outer rotor. The air for the bearing and drive of the inner rotor is fed through two cylinders (part 10) which fit inside the two pockets (part 10') on the outer rotor with a very small clearance. The minimal clearance allows the outer rotor to spin freely without significant leakage of air.

It is well known that a spinning object, like the inner rotor, has a tendency to maintain its spinning orientation unless a torque is exerted on it. Under DOR the spinning orientation of the inner rotor changes direction rapidly. Thus, a torque has to be provided to the inner rotor by the bearing system which only has a limited load capacity. This extra burden imposed by the torque may cause a 'crash' of the inner rotor spinning. Fortunately, nature provides a self-adjusting mechanism which can reduce the torque to a tolerably small value under DOR.

A perfectly balanced inner rotor requires not only axial symmetry with respect to the rotation axis of the inner rotor but also mirror symmetry with respect to the plane which is perpendicular to the rotation axis of the inner rotor and contains the cross-point of the inner and outer rotor rotation axes. The equation governing this motion is

$$\tau = \frac{d\mathbf{J}}{dt} \quad (21)$$

where $\mathbf{J}$ is the angular momentum of the inner rotor and τ is the torque applied to the inner rotor through the bearing. The angular momentum can be expressed in terms of the angular velocity ($\omega_{x''}$, $\omega_{y''}$, and $\omega_{z''}$)

$$\mathbf{J} = iI_{x''}\omega_{x''} + jI_{y''}\omega_{y''} + kI_{z''}\omega_{z''} \quad (22)$$

where i , j , and k are the unit vectors of the PAS (x'' , y'' , z'') of the moment of inertia tensor of the inner rotor with principal values $I_{x''}$, $I_{y''}$, and $I_{z''}$. For a cylindrical inner rotor, z'' is chosen to be along the rotation axis of the inner rotor, y'' is in the plane containing the rotation axes of both the inner and the outer rotors, and $I_{x''} = I_{y''}$. There are two contributions to the inner rotor angular velocity $\omega_{z''}$, the angular velocity ω_r originating from the inner rotor rotation around its own axis and the angular velocity $\omega_R \cos \beta_1$ imposed by the rotation of the outer rotor as illustrated in Figure 2(a). The only contribution to $\omega_{y''}$, $\omega_R \sin \beta_1$, comes from the rotation of the outer rotor, whereas $\omega_{x''} = 0$. The total angular momentum $\mathbf{J}$ is the vector sum of the two components $I_{z''}(\omega_r + \omega_R \cos \beta_1)\mathbf{k}$ and $I_{y''}\omega_R \sin \beta_1\mathbf{j}$. It is clear that if this vector sum $\mathbf{J}$ is along the rotation axis of the outer rotor, the total angular momentum will become time-independent; thus, no torque is involved in the motion of the inner rotor. This torque-free condition can

Figure 4 A double-rotor probe design. (a) DOR probe. (b) Details of the double rotor. The numbers, which apply both to (a) and (b), indicate 1, inner rotor with flutes at both ends; 2 and 2', building blocks of the double rotor held together by the axles 13 with matching counterparts 13', and the step-shoulder 14 with matching counterparts 14'; 3 and 4, air channels and holes for the bearing and drive system of the inner rotor; 5, pins to hold the inner rotor in place; 6 and 7, the bearing and drive system for the outer rotor; 8, air exhaust holes for the outer rotor; 9, pins to hold the outer rotor in place; 10, air passage for the inner rotor which fits into the pocket 10' with minimal clearance; 11, space for the rf coil; 15, caps holding the inner rotor in place and allowing air escape for the inner rotor system

be realized if

$$\tan \beta_1 = \frac{I_{y''} \omega_R \sin \beta_1}{I_{z''} (\omega_r + \omega_R \cos \beta_1)} \quad (23)$$

or

$$\frac{\omega_r}{\omega_R} = \cos \beta_1 \left(\frac{I_{y''}}{I_{z''}} - 1 \right) \quad (24)$$

The ratio $I_{y''}/I_{z''}$ is determined by the shape of the inner rotor. Consequently, the ratio ω_r/ω_R corresponding to the torque-free condition is also determined by the spinner design. The

typical value of the ratio ω_r/ω_R is around 5–6 with the inner rotor spinning at about 5 kHz and the outer rotor spinning at 1 kHz. In practice, there is no need to adjust the spinning speeds of the inner and outer rotors manually to satisfy the torque-free condition because a self-adjusting mechanism is in place.¹⁰ To operate the double rotor, the inner rotor is first brought to a high speed. Then the outer rotor speed is slowly increased. Initially, the ratio ω_r/ω_R is too high for the torque-free condition. Consequently, a torque is generated, and the friction on the inner rotor generated by this torque slows down the spinning of the inner rotor. As a result, the ratio ω_r/ω_R is reduced, thus the torque and friction also decrease. Finally,

the system stabilizes the inner rotor spinning speed at a ω_r/ω_R ratio close to the torque-free condition. As the outer rotor speed increases, the inner rotor speed increases as well to maintain the torque-free condition.

4 SIDEBAND SUPPRESSION BY SYNCHRONIZATION

Since the spinning speeds of the inner and outer rotors are limited by the current technology, the DOR spectrum often consists of a large number of intense sidebands along with the centerband, as can be seen clearly in Figure 3(c). These sidebands may cause severe problems in practical applications. For instance, the sidebands associated with one lattice site may overlap with the centerband associated with another crystallographically inequivalent site. Such interference makes the recognition of crystallographically inequivalent sites difficult. In principle, the centerband can be distinguished from the sideband by changing the spinning speed of the outer rotor, because the resonance frequency of the centerband does not vary with the change of the spinning speed whereas the sideband does. However, this method is ineffective when the residual linewidth as a result of the random distribution of local environment becomes comparable to the spinning speed of the outer rotor. Therefore, the suppression of spinning sidebands is very important for practical applications.

To simplify the problem, consider the case where the spinning rate of the inner rotor is infinite. Under this condition, equation (18) can be reduced to

$$Y_{l,m}(\beta, \alpha) = \sum_{m''=0}^l \sqrt{\frac{(2l+1)}{4\pi}} \times D_{0,m}^{(l)}(\alpha^i, \beta^i, \gamma^i) d_{m'',0}^{(l)}(\beta_1) d_{0,m''}^{(l)}(\beta_2) \times 2 \cos[m''(\omega_R t + \alpha_1)] \quad (25)$$

The $m'' = 0$ term in equation (25) is zero under the DOR condition. As mentioned earlier, the effect of motion under DOR can be treated as an adiabatic process. Thus, the evolution of the NMR signal $s(t)$ associated with the central transition can be described by

$$s(t) \propto \exp[i\varphi(t)] \quad (26)$$

The accumulated phase $\varphi(t)$, according to equation (25), can be calculated by^{13,14}

$$\varphi(t) = \omega_0 t + \int_0^t dt' \sum_{m=1}^4 a_m \cos[m(\alpha_1 + \omega_R t')] \quad (27)$$

where ω_0 is the angular isotropic resonance frequency including the Larmor frequency and the isotropic second-order quadrupolar shift, and the time $t = 0$ corresponds to the timing of the rf excitation pulse. The detailed expressions of the coefficients a_m have no bearing on our following discussion. The expression of equation (27) is quite simple for the case of $\alpha_1 = 0$ or $\alpha_1 = 180^\circ$, which can be selected by synchronizing

the rf excitation pulse with the position of the rotor. The accumulated phase $\varphi(t)$ is¹³

$$\varphi(t) = \omega_0 t + \xi_{\text{even}} \pm \xi_{\text{odd}} \quad (28)$$

where the upper and lower signs correspond to the $\alpha_1 = 0$ and $\alpha_1 = 180^\circ$ cases, respectively, and

$$\xi_{\text{even}} = \frac{a_2}{2\omega_R} \sin(2\omega_R t) + \frac{a_4}{4\omega_R} \sin(4\omega_R t) \quad (29a)$$

$$\xi_{\text{odd}} = \frac{a_1}{\omega_R} \sin(\omega_R t) + \frac{a_3}{3\omega_R} \sin(3\omega_R t) \quad (29b)$$

The real part (the X channel) of the signal is given by

$$\begin{aligned} \cos \varphi(t) &= \cos(\omega_0 t) (\cos \xi_{\text{even}} \cos \xi_{\text{odd}} \mp \sin \xi_{\text{even}} \sin \xi_{\text{odd}}) \\ &\quad - \sin(\omega_0 t) (\sin \xi_{\text{even}} \cos \xi_{\text{odd}} \\ &\quad \pm \cos \xi_{\text{even}} \sin \xi_{\text{odd}}) \end{aligned} \quad (30)$$

It can be shown that the above expression of $\cos \varphi(t)$ can be expanded in the following form:^{13,14}

$$\begin{aligned} \cos \varphi(t) &= \sum_{k=-\infty}^{\infty} \{A_{2k} \cos[(\omega_0 + 2k\omega_R)t] \\ &\quad \pm B_{2k+1} \cos[(\omega_0 + (2k+1)\omega_R)t]\} \end{aligned} \quad (31)$$

where A_{2k} and B_{2k+1} are coefficients which are independent of time t . This expression of $\cos \varphi(t)$ can be derived by using the series expansion for the functions $\cos(z \sin \theta)$, $\sin(z \sin \theta)$, $\cos(z \cos \theta)$, and $\sin(z \cos \theta)$. For instance,

$$\cos(z \sin \theta) = J_0(z) + 2 \sum_{k=1}^{\infty} J_{2k}(z) \cos(2k\theta) \quad (32)$$

where the coefficients J_0 and J_{2k} are the Bessel functions. Based on these expansions, it can be shown that the terms $\cos \xi_{\text{even}} \cos \xi_{\text{odd}}$ and $\sin \xi_{\text{even}} \cos \xi_{\text{odd}}$ in equation (30) contribute only to the terms $A_{2k} \cos[(\omega_0 + 2k\omega_R)t]$ in equation (31); these terms represent the centerband and the even-numbered rotational sidebands. Similarly, it can be shown that the terms $\sin \xi_{\text{even}} \sin \xi_{\text{odd}}$ and $\cos \xi_{\text{even}} \sin \xi_{\text{odd}}$ in equation (30) contribute only to the terms $B_{2k+1} \cos[(\omega_0 + (2k+1)\omega_R)t]$ in equation (31); these terms represent the odd-numbered rotational sidebands. Therefore, the centerband and the even-numbered sidebands do not change when α_1 changes from 0 to 180° whereas the odd-numbered sidebands change sign. Thus, the odd-numbered sidebands can be cancelled completely by alternating the acquisition between $\alpha_1 = 0$ and $\alpha_1 = 180^\circ$ using synchronization. It is also clear from equation (31) that the real part of the signal is in the pure absorptive phase. Similar arguments can be applied to the imaginary part (the Y channel) of the signal, and it is in the pure dispersive phase. Figure 5 shows the unsynchronized ^{23}Na DOR spectra and the corresponding synchronized spectra in sodium oxalate for two different outer rotor speeds, 604 and 800 Hz. Indeed, addition of the spectra obtained at $\alpha_1 = 0$ and $\alpha_1 = 180^\circ$ eliminates the odd-numbered sidebands. The sideband pattern can be simulated using values of $\chi = 2.43$ MHz and $\eta = 0.77$, assuming that the sidebands arise mainly from the

second-order quadrupole interaction. In general, however, the DOR sideband pattern also contains contributions of other interactions such as CSA.

5 CP DOUBLE ROTATION

The technique CP MAS has become one of the most important techniques in solid state NMR.¹⁵ High sensitivity or selectivity based on the proximity between two kinds of nuclei (e.g. ^{13}C and ^1H) is provided by the CP process, whereas high resolution is achieved by MAS and decoupling. Although CP MAS can be useful for half-integer quadrupolar nuclei, its application is restricted by the limited resolution of MAS. Therefore, it is a natural step to combine CP with DOR, which will provide the proximity information with high resolution.

In a CP experiment involving spin- $\frac{1}{2}$ nuclei (e.g. ^1H) and the observing half-integer quadrupolar nuclei S , a transverse magnetization of the I spins is first created by a 90° pulse. This is followed by simultaneously turning on resonant rf fields for both I and S nuclei over a time duration τ_c (the contact time). It is well known that the transverse magnetization of the I spins can be transferred efficiently to the magnetization of the S spins through the spin-spin interaction under the Hartmann-Hahn condition.^{16,17} For half-integer quadrupolar nuclei with quadrupole interactions much larger than the interaction of the rf field with the S spin, the Hartmann-Hahn condition can be formulated as^{18,19}

$$\omega_{II} = (S + \frac{1}{2})\omega_{IS} \quad (33)$$

where S is the spin quantum number for the S nuclei and ω_{II} and ω_{IS} are the rf amplitudes associated with the I and S nuclei, respectively.

Since the spin-spin interaction decreases rapidly as the distance between two spins increases, CP provides useful information on the proximity between the I and S nuclei. The fact that CP DOR can provide such proximity information with high resolution makes this technique very useful in the study of materials.²⁰ This point is illustrated by the application of CP DOR in $\text{AlPO}_4\text{-11}$, an aluminophosphate molecular sieve with linear channels. There are five phosphorus and five aluminum crystallographically distinct sites²¹ with a 1:1:1:1:1 ratio in $\text{AlPO}_4\text{-11}$. Figure 6(a) shows a proton-decoupled ^{27}Al DOR spectrum with an outer rotor spinning speed $\nu_L = 725$ Hz. All five resonance lines including an octahedral peak at -19.6 ppm are revealed by DOR. The four tetrahedral peaks are at 43.8, 39.8, 38.2, and 28.0 ppm, respectively. Other peaks in the spectrum are spinning sidebands. Figure 6(b) shows a proton-decoupled CP DOR spectrum with $\nu_L = 725$ Hz and a contact time $\tau_c = 300$ μs . The proton nutation frequency (5 kHz) is matched to the nutation frequency of the ^{27}Al central transition. No signal is observable under the mismatched condition. The octahedral aluminum sites are formed by chemisorption of two adsorbed water molecules. Therefore, it has a stronger coupling with the protons than the tetrahedral sites do. It is of interest that the tetrahedral peak at 28.0 ppm shows up only weakly in the CP DOR spectrum, indicating that the corresponding site is avoided by adsorbed water molecules.

The technique of DOR is not only effective for eliminating the second-order quadrupolar broadening, but also for

Figure 5 The effects of synchronizing the outer rotor at angles $\alpha_1 = 0$ and $\alpha_1 = 180^\circ$ with rf pulses on the DOR spectra of ^{23}Na in polycrystalline sodium oxalate. (a) Unsynchronized and synchronized spectra with the outer rotor spinning at 604 Hz. A computer simulation is also shown with $\chi = 2.43$ MHz and $\eta = 0.77$. (b) Similar spectra obtained with the outer rotor spinning at 800 Hz. The computer simulation uses the same parameters as in (a)

Figure 6 (a) Aluminum-27 DOR spectrum of $\text{AlPO}_4\text{-11}$ with the outer rotor spinning at 725 Hz with proton decoupling; (b) CP DOR spectrum with the outer rotor spinning at 725 Hz with proton decoupling and a contact time of 300 μs . The ^{27}Al signal in dilute aqueous $\text{Al}(\text{NO}_3)_3$ solution was used as the chemical shift reference

removing dipole–dipole interactions.²² This feature is very important for observations of abundant nuclei with high gyromagnetic ratios such as ^{27}Al , ^{23}Na , and ^{11}B . Since its first experimental demonstration in 1988¹ examples of useful applications include DOR NMR studies of minerals,^{3,23} molecular sieves,^{20,22,24,25} and zeolites.^{26,27} This list is incomplete by far, and is still growing.

1 INTRODUCTION

Double-quantum (DQ) NMR spectroscopy of dipolar coupled spins in solids under fast magic angle spinning (MAS) is new a tool, by use of which topics of general interest in materials science and bioscience can be addressed. For instance, in advanced synthetic as well as in biological systems self assembly of carefully chosen building blocks is of central importance.^{1–4} Hydrogen bonding and aromatic π - π interactions are key features of supramolecular chemistry.⁵ Despite being highly ordered on a local scale, such systems often do not crystallize. Therefore, their structures cannot be determined by conventional X-ray crystallography or neutron scattering. Alternatives are needed which should provide structural and dynamic information, preferably requiring only small amounts of as-synthesized samples, without the need for isotopic labeling. High resolution solid state ^1H -NMR can meet these requirements,^{6–8} provided that sufficiently selective information can be extracted from the corresponding spectra.

Since 1994 we have systematically pursued the development of solid state ^1H NMR for that purpose by combining fast MAS⁹ and DQ NMR spectroscopy,¹⁰ which makes use of the homonuclear dipole–dipole coupling between protons.^{11,12} The spectral resolution can be increased by use of similar methods exploiting heteronuclear ^1H – ^{13}C dipole–dipole couplings.¹³ These techniques take advantage of the significant simplification of the multispin dipolar coupled network under fast MAS, where two-spin correlations predominate,¹⁴ and have provided new insight in

- hydrogen bonded structures in the solid state¹⁵
- columnar stacking and molecular dynamics of discotics¹⁶
- chain order and translational motion in polymer melts¹⁷
- chain organization on surfaces.¹⁸

This review briefly outlines these new approaches for studying supramolecular organization and demonstrate their advantages with specific examples.

2 HIGH RESOLUTION SOLID STATE NMR

Various aspects of solid state NMR are subjects of other articles in this Encyclopedia. For a full treatment of earlier work including multidimensional techniques, we refer to our extended monograph.¹⁹

2.1 Magic Angle Spinning

A particularly important recent advance in solid state NMR is fast MAS with rotor frequencies $\omega_R > 2\pi \cdot 25 \text{ kHz}$ ⁹ up to $2\pi \cdot 50 \text{ kHz}$ as described by Samoson (see **Magic-angle Spinning Extensions**).²⁰ For most organic solids, the strongest ^1H – ^1H dipole–dipole coupling, e.g., in CH_2 groups with a proton–proton distance of 0.18 nm are of the order of $\omega_D \approx 2\pi \cdot 20.6 \text{ kHz}$. Thus, the condition $\omega_R \geq \omega_D$ can be met even for the strongest dipole–dipole couplings. Since in most cases the remaining spins are further away, the corresponding remote couplings can effectively be ‘spun out’

Figure 1 (a) Simulated MAS NMR spectra for a spin-pair subject to a perturbing spin in an isosceles triangle arrangement for various ratios ξ of the perturbing dipole–dipole coupling ω_D^{pert} to the rotor frequency ω_R . (b) Centreband ($n = 0$) and sideband ($n = 1, 2$) intensities in MAS spectra for the three-spin system in (a) as function of ξ . Solid lines, two- and three-spin correlations; dotted lines, only two-spin correlations.²¹ (Reproduced by permission of Academic Press)

and only the strongest couplings, originating from the shortest distances, are retained. This simple picture is indeed borne out in an elaborate theoretical treatment of multi-spin systems under fast MAS, combining Floquet theory and perturbation theory.¹⁴ The higher-spin contributions are found to scale with increasing powers of the inverse rotor frequency and become less and less important at higher and higher ω_R .

As an example, Figure 1(a) shows MAS NMR spectra for a spin-pair subject to a perturbing spin in an isosceles triangle arrangement for various ratios ξ of the perturbing dipole–dipole coupling ω_D^{pert} to the rotor frequency ω_R .²¹ Sideband patterns are observed, from which the dominant dipole–dipole coupling D^{pair} can be determined straightforwardly as indicated in Figure 1(b). The simulated center and sideband intensities, calculated from simply adding the contributions of pair correlations are very good approximations for the full treatment including three-spin correlations. The linewidths, however, significantly increase with ξ as the dominant term there involves three-spin correlations. Thus, the strongest dipole–dipole couplings can simply be determined from one-dimensional (1D) MAS sideband patterns.

2.2 Homonuclear Double-Quantum Coherences

In order to obtain a structure, the weaker remote dipole–dipole couplings, relating protons of different chemical entities are particularly informative. They can now be determined

by DQ MAS NMR spectroscopy.^{11,12} The basic experimental scheme, a specific pulse sequence and a coherence pathway diagram,²² are shown in Figure 2(a): firstly, a double-quantum coherence (DQC) is excited, which subsequently evolves during an incremented time period t_1 . Afterwards, the DQC is converted into observable single-quantum coherence (SQC), which is detected in the acquisition period. Pure absorption mode 2D spectra are ensured by generating amplitude modulated signals in t_1 through proper selection of symmetric pathways.^{19,22} During excitation and reconversion the *homonuclear* dipole–dipole interaction is recoupled. Numerous ways for achieving this have been developed, as described by Levitt (see **Symmetry-Based Pulse Sequences in Magic-Angle Spinning Solid-State NMR**)²³ (see also Ref.²⁴)

The nature of the corresponding 2D spectra is illustrated in Figure 2(b,c). Here we consider two kinds of pairs of spins, labeled 1 and 2, with different chemical shifts. The excitation of DQ coherence is based on the dipole–dipole coupling between the two spins involved. Thus, if the two kinds of groups are separated (Figure 2(b)), DQ signals can only occur at $2\omega_1$ and $2\omega_2$ along the DQ dimension, i.e., on the diagonal of a 2D plot with proper frequency scaling. These signals reflect the dipolar couplings within the respective groups. Note that distinct from the INADEQUATE experiment in isotropic liquids based on the isotropic scalar

Figure 2 (a) Pulse sequence and coherence transfer pathway of a homonuclear DQ MAS experiment, all pulses have 90° flip angles. (b) Scheme of DQ MAS NMR spectrum for separated spin pairs, (c) for spin pairs in spatial proximity

couplings,²² the intragroup coherences occur despite the fact that the isotropic chemical shifts of the two spins are equal. This reflects the fact that in solids the DQ coherence is generated by the anisotropic dipole–dipole coupling. If the groups are intermixed (Figure 2(c)), DQ coherences between spins of different groups can also be excited. They occur at the sum-frequency $\omega_1 + \omega_2$ in the DQ dimension and can be detected at both frequencies ω_1 and ω_2 in the single quantum dimension. Thus, such a pair of lines in the 2D-NMR spectrum directly maps the spatial proximity between group 1 and group 2. For short excitation times the intensities of the DQ signals are proportional to D_{ij}^2 where D_{ij} describes the dipole–dipole coupling between the two spins involved.

Spectra as discussed in the previous section are obtained in a *rotor-synchronized fashion*, i.e., the t_1 increment is set equal to the rotor period τ_R and yield distance constraints for the dipolar coupled nuclei. More accurate values for dipole–dipole couplings may be obtained from build-up curves of DQC, which for isolated spin pairs, such as doubly labeled ^{13}C – ^{13}C , exhibit an oscillatory behavior.²⁵ Strongly coupled ^1H – ^1H

systems, however, quickly develop multi-spin character and the oscillations are damped out. Nevertheless, even there the initial build-up is dominated by DQCs and can quantitatively be analyzed.^{26,27}

The dipole–dipole coupling constants as well as the geometry of dipolar coupled clusters as, e.g., in triple- or quadruple hydrogen bonds, can much better be elucidated if DQ *spinning sidebands* are generated by choosing a t_1 time increment well below τ_R .^{11,12} Examples calculated for an isolated spin pair are plotted in Figure 3 as a function of $D_{ij}\tau_{\text{exc}}$. Note that these sidebands occur despite the fact that the DQC for an isolated spin-pair does not evolve during the evolution time t_1 . Instead, the *reconversion* is *rotor encoded* because the dipole–dipole Hamiltonian modulated by MAS differs at the beginning of excitation and reconversion. This mechanism is termed *reconversion rotor encoding* (RRE) and occurs whenever the Hamiltonians involved have an amplitude modulation on the rotor phase, which is also the case in MQ MAS experiments on quadrupolar nuclei.^{28,29} The two cases have been compared in detail.³⁰ In actual applications, the rotor frequency ω_R and the excitation time τ_{exc} will be chosen to generate up to third

Figure 3 DQ spinning sideband patterns calculated for increasing values of the product of the dipolar coupling and the excitation time

Figure 4 Pulse sequence for heteronuclear ^1H – ^{13}C correlation experiments based on combining the concepts of REDOR and HMQC. For details see Ref.³⁸ Solid and open bars indicate 90° and 180° pulses, respectively. (Reproduced by permission of American Institute of Physics)

order sidebands in order to achieve sufficient signal-to-noise ratios, yet avoid multi-spin effects, which lead to *evolution rotor modulation* (ERM).³⁰ Notably, multi-spin effects give rise to additional (even-order) sidebands and can, therefore, be easily identified.

2.3 Heteronuclear Multiple-Quantum Coherences

Two-dimensional ^1H DQ MAS experiments as described in Section 2.2 still suffer from the limited spectral resolution in solid state ^1H NMR. Therefore, heteronuclear methods involving ^{13}C or ^{15}N offer significant advantages for obtaining more specific distance constraints. Indeed, if combined with homonuclear ^1H – ^1H decoupling by rotor synchronized multiple pulse sequences³¹ or frequency switched Lee-Goldburg experiments,³² remarkable resolution has been achieved in model compounds³³ as well as biologically relevant systems.³⁴ Once specific ^1H – ^{13}C spin pairs are identified, precise measurement of their dipole–dipole couplings via spinning sidebands also offers a new and efficient way to study molecular dynamics in analogy to ^2H -NMR experiments,¹⁹ yet without the need for elaborate isotope labeling. Rotational-echo double-resonance (REDOR)^{35,36} currently is most popular for determining heteronuclear dipole–dipole couplings in solids. It is based on a particularly simple approach of *recoupling*, i.e., the application of equally spaced π -pulses twice per rotor period on one of the isotopes. When applied under fast MAS in order to efficiently reduce the homonuclear dipole–dipole coupling, REDOR can be combined with multiple-quantum spectroscopy in a whole class of dipolar heteronuclear multiple spin correlation (DIP-HMSC) experiments^{37,38} which are more selective than determining distance constraints via cross polarization and spin diffusion experiments.^{39,40} The basic pulse sequence for a ^1H – ^{13}C heteronuclear multiple-quantum correlation (HMQC) experiment is depicted in Figure 4. As in homonuclear DQ-NMR, the first half of the REDOR recoupling is identified as the excitation period, and the second as the reconversion period. In between, HMQC evolution occurs during t_1 . The ^{13}C chemical shift is fully refocused by π -pulses during excitation, evolution and reconversion.

Similar to the homonuclear case, Section 2.2, precise values for heteronuclear dipole–dipole couplings can be determined via sideband patterns, which are generated through rotor encoding (RRE) as well as evolution (ERM). Consequently, the sideband patterns for an isolated heteronuclear spin pair, plotted as a function of the excitation time in Figure 5(a), exhibit the same features as in the homonuclear case (Figure 3). Again, in actual experiments the excitation times are chosen short enough such that a limited number of sidebands is created and multi-spin effects are minimized for C–H groups. The unavoidable three-spin coherences in rigid CH_2 groups, in fact, lead to efficient dephasing.^{37,38} This can be used for spectral simplification, but also offers an easy way to distinguish mobile methylene groups from rigid ones.

DQ sideband patterns also offer new ways to study the rate and the geometry of rotational motions,^{16,38} where the site selectivity is particularly high for heteronuclear DQ coherences. In Figure 5(b) simulated sideband patterns are plotted for the C–H group which is a sensitive probe of phenylene rotation, often met in practice.¹⁹ At low temperatures one

Figure 5 (a) Calculated HMQC spinning sideband patterns for a single IS spin pair for increasing values of the ratio of the product of the dipolar coupling strength D_{IS} multiplied by the number of pump cycles N_{rcpl} and the rotor frequency ω_{R} . For details see.³⁸ (b) Calculated heteronuclear DQ MAS NMR spinning sideband patterns for rotating phenylene groups and different flip angles α as indicated ($N_{\text{rcpl}}D_{\text{IS}}/\omega_{\text{R}} = 1.67$). (Reproduced by permission of American Institute of Physics)

would expect small-angle librations. With increasing temperatures the angular excursions will increase until full rotation might be reached. The resulting motionally averaged dipolar couplings are readily calculated via the internet by use of our NMR-WEBLAB.⁴¹ As shown in Figure 5(b), the sideband patterns show a marked dependence of the flip angle α . A recent experimental example is provided by the restricted phenylene motion in polyphenylene dendrimers,⁴² a new type of nanomaterials.¹

3 APPLICATIONS

3.1 Spin Counting

The classic application of MQ NMR in solids as pioneered by A. Pines in the early 1980s is spin counting.⁴³ He showed that it is possible to excite homonuclear MQCs comprising more than 100 spins, by exploiting the through-space dipole–dipole coupling. With this technique it was possible, for instance, to prove the existence of small clusters of proton spins on the surface of silica catalyst supports.⁴⁴ In fact, the growth of MQCs in a spin cluster as depicted in Figure 6(a) can be described by a statistical model. The intensities of the

coherence orders follow a Gaussian distribution, the width of which increases with excitation time. Such behavior indicates that the build-up of homonuclear MQCs amongst strongly coupled spins occurs via a random walk. The different pathways indicated in Figure 6(a) result from the non-localized and, therefore, non-selective growth of the spin-cluster. As demonstrated in Figure 6(c), this behavior is also found under MAS conditions, provided efficient recoupling is achieved.²⁷

Distinct from that, MQCs in the I-spin subspace of a heteronuclear IS NMR experiment are excited via the dipole–dipole coupling of all these spins to a single S spin. For this selected site the multitude of surrounding I spins creates

Figure 6 Growth of spin clusters as probed in homonuclear (a) and heteronuclear (b) MQ NMR experiments. Experimental examples for adamantane ($^1\text{H} \cdots ^1\text{H}$ homonuclear, (c)), for details see Ref.²⁷ and L-alanine ($^1\text{H} \cdots ^{13}\text{C}$ heteronuclear, (d)), for details see Ref.³⁸ (Reproduced by permission of American Institute of Physics, (a), (b), (d) and Academic Press, (c))

a local field. The number of proton (I) spins incorporated in the HMQ can only grow by including remote spins with sufficient couplings to the S spin [Figure 6(b)]. Thus, build-up of higher spin coherences will converge with time. As shown in Figure 6(d), higher order MQCs are indeed observed for the carboxyl carbon in uniformly ^{13}C labeled L-alanine,³⁸ but the intensity distribution obviously is not Gaussian. Thus, heteronuclear spin counting indeed probes a selected local environment and therefore is anticipated as a new tool for structural investigations.

3.2 Structure

3.2.1 Hydrogen Bonding

Protons in hydrogen bonded structures exhibit ^1H chemical shifts well away from the aliphatic peaks. Therefore, high

resolution ^1H solid state NMR is ideally suited for investigating such systems as noted early on.⁴⁵ Moreover, correlations between the ^1H isotropic chemical shifts and the hydrogen-bond strength specified by $\text{O}\cdots\text{H}$ or $\text{O}\cdots\text{O}$ distances from single-crystal analyses have been established.⁴⁶ The first example of the new kind of information about proton–proton distance constraints available from solid state DQ MAS NMR was the investigation of the unusual hydrogen bonded structures in benzoxazine dimers.¹⁵ These dimers are of interest as model compounds for a new class of phenolic materials, the polybenzoxazines prepared by Ishida and coworkers.⁴⁷ These systems combine several favorable properties, such as near-zero shrinkage on polymerization as well as low water absorption, which are attributed to their favorable hydrogen-bonding.

Figure 7(a) shows the superimposed ^1H MAS NMR spectra of both the methyl (solid line) and ethyl (dashed line)

Figure 7 (a) ^1H MAS NMR spectra of benzoxazine dimers at 500 MHz. Solid line, methyl derivative; dotted line, ethyl derivative. (b), (c) Low field region of the ^1H DQ MAS NMR spectrum of the methyl and ethyl derivative, respectively. (d), (e) Schematic arrangement of the methyl dimers into pairs (d) and the ethyl dimers into extended chains (e). For details see Ref.¹⁵ (Reproduced by permission of American Chemical Society)

derivative. The spectra differ markedly in the low-field region, which gives a first hint towards different hydrogen bond arrangements in the two cases. The differences are even more marked in the ^1H DQ MAS NMR spectra, whose low-field regions are displayed in Figures 7(b) and 7(c). The labels (A, B, C, and D) refer to the SQ resonances of the hydrogen bonded, aromatic, and aliphatic protons, respectively. The peaks in the DQ spectrum indicate proximities of protons within about 0.35 nm^{15} and are labeled accordingly as AB, AC, etc. The most striking differences between the methyl- and ethyl-dimer spectra are the strong aromatic auto peak (CC) and only weak intensity (AC) indicating a DQC between a $\text{O}\cdots\text{H}\cdots\text{N}$ and an aromatic proton for the methyl-dimer, while the situation is reversed for the ethyl-derivative. As discussed in detail elsewhere,¹⁵ this indicates pair formation from two dimers, Figure 7(d) in the methyl-derivative, and extended hydrogen bonded chains, Figure 7(e) for the ethyl-dimers.

These structural differences have meanwhile been confirmed by X-ray diffraction.

Another example of elucidating complex hydrogen bonded structures is provided by our study of supramolecular polymers⁴⁸ coupled via quadrupole bonds in 2-ureido-4-pyrimidone units, where keto- and enol tautomers in the solid state could clearly be distinguished by DQ MAS NMR.⁴⁹ DQ spinning sideband patterns have also been used to locate the protons in bilirubin, a compound of considerable medical importance. It is a product of the metabolism of hemoglobin from red blood cells. Due to an unusually strong intramolecular hydrogen bonding arrangement, bilirubin itself is insoluble in water and can only be removed from the body after being conjugated enzymatically with glucuronic acid.⁵⁰ Inefficient removal of bilirubin from the body manifests itself as jaundice. Solid state NMR now has provided proton-proton distances with an accuracy of $\pm 0.002\text{ nm}$ in this important system.⁵¹

Experimental ^1H spectra of HBC- C_{12} together with staggered arrangement (c). For details see Ref.⁵⁴ (Reproduced by permission of American Chemical Society)

3.2.2 Aromatic π - π Interactions in Columnar Structures and Guest-Host Complexes

In addition to hydrogen-bonding, the ^1H chemical shifts are very sensitive to ring currents associated with π -electrons in aromatic moieties.⁵² While in solution, the isotropic molecular tumbling removes most of the π -shifts, in the solid state the protons are exposed to the π -electrons of nearby aromatic moieties, be they intra- or intermolecular. The latter information is particularly valuable for elucidating supramolecular structures.^{2,5} A clear-cut example is provided by the columnar stacking of substituted hexa-*peri*-hexabenzocoronene (henceforth referred to as HBC). Opposed to solution or the liquid crystalline phase, where the discs tumble isotropically or rotate rapidly around the column axis, in the solid three distinct aromatic lines are observed in the aromatic region of the ^1H -NMR spectrum¹⁶ (Figure 8). The DQ-spectrum exhibits a strong CC auto and two AB cross peaks, which implies the presence of only two types of pairs of aromatic protons, $\text{H}_\text{A}-\text{H}_\text{B}$, $\text{H}_\text{C}-\text{H}_\text{C}$. For quantitative analysis, advanced quantum chemical calculations of NMR chemical shifts are needed.⁵³ They show that staggered arrangements of the HBC moieties indeed give rise to π -shifts of several ppm.⁵⁴ The assignment, which of the chemically shifted protons form pairs is achieved by DQ-NMR and is essential to determine the type of staggering. In a herringbone-structure which corresponds to that of unsubstituted HBC (Figure 8(a)) none of the carbons are aligned, whereas in structure (b) half of the carbons are located directly above or below a carbon of the adjacent layer resembling the packing in graphite. The latter (Figure 8(b)) could clearly be excluded, because it does not match the experimental 2D NMR pattern (Figure 8(c)). The pattern in Figure 8(a), however, agrees well with the experimental one. This proves the specific packing arrangement hypothesized earlier,¹⁶ that this alkylsubstituted system adopts the structure of unsubstituted HBC itself. Through-space π -shifts are remarkably long-range, with an aromatic ring at a distance of 0.7 nm still exerting a measurable influence. Thus, in the final simulation, three HBC moieties had to be taken into account (Figure 8(c)).

The combination of ^1H DQ MAS-NMR with advanced ab initio quantum chemical calculations also proved essential for elucidating the structure of a supramolecular guest-host complex. The receptor shown in Figure 9(a) belongs to the family of molecules termed molecular tweezers due to their concave-convex topology and ability to selectively form complexes with electron-deficient compounds.⁵⁵ An X-ray crystal structure is available for this system, offering an opportunity to check the reliability of the spectroscopic approach.⁵⁶ Figure 9(b) presents a rotor-synchronized ^1H DQ MAS spectrum of the complex (Figure 9(a)). Despite the high field (700 MHz) used, the spectral resolution for the many aromatic protons is unsatisfactory. The different sites can much better be distinguished in a heteronuclear correlation spectrum (Figure 9(c)) which was recorded with the REPT-HSQC experiment.³⁷ The two overlapping ^{13}C lines at 128.7 and 129.6 ppm are assigned to the guest CH groups (5a and 5b), which are well separated by 3.6 ppm in the ^1H -dimension. This demonstrates that the π -shifts are much more significant for the protons than they are for the carbons.^{54,56} In the present case, the binding of the electron-deficient 1,4-dicyanobenzene guest in the complex is such that the symmetry of the molecular tweezer is broken (Figure 9(a)) and the two adjacent

guest protons experience the π -shifts due to the host to largely different degrees. Moreover, the end pair of aromatic protons are directed into the ring current of the naphthalene unit of the next host, which explains the π -shifted 4 ar^{II} resonance.⁵⁶ Thus both, the guest-host complexation, as well as the packing of the “loaded” tweezers within the supramolecular solid can be probed by solid state NMR and quantified by ab initio calculation.

3.2.3 Surface Studies

The high sensitivity of ^1H NMR makes it possible to study defect sites and molecules adsorbed at surfaces in a straightforward way.⁴⁴ Two examples are discussed. The first concerns a ^1H -MQ MAS NMR study of defect sites in a zeolite.⁵⁷ As in supramolecular systems, the structures of defects are difficult to study in these industrially important microporous solids,⁵⁸ because the defects are usually not ordered in the crystallographic sense and, therefore, are not easily amenable to analysis by diffraction methods. Figure 10(a) shows the 2D ^1H DQ MAS NMR spectrum of an as-made all silica ZSM-12 zeolite.⁵⁷ The signal at 10 ppm in the SQ dimension is due to a DQC generated by the cluster of silanol protons of the defect site. The observation of a strong centreband in the ^1H DQ MAS spinning sideband pattern (Figure 10(b)) proves that at least three silanol groups are engaged in hydrogen bonding within the defect site. These results have important implications concerning the nucleation mechanism of high-quality zeolites, as they provide new information on the structure of charge-compensating units in the zeolite colloidal precursors.

In another example ^1H DQ MAS NMR recently has also provided new insight in the packing of polyelectrolyte multilayers (PEMs) on silica colloids.¹⁸ These systems, generated by alternate adsorption of anionic and cationic polymers are being explored for numerous applications ranging from photonics to enzyme encapsulation.^{59,60} Fast MAS NMR at high fields (700 MHz) of such systems is able to distinguish, e.g., water adsorbed at the surface from that in the PEM and the silanol groups. Two-dimensional ^1H DQ MAS NMR, however, is needed to probe the organization of the polyelectrolytes within the multilayers. The DQ spectra (Figure 10) exhibit cross-peaks between the aromatic protons of the poly(styrene sulfonate) (PSS) polyanion and the poly(diallyldimethyl-ammonium) (PDADMAC) polycation in both, the bulk complex and the multilayers. These findings¹⁸ are consistent with conclusions based on less direct experimental probes that these polyelectrolyte multilayers are structurally very similar to the corresponding bulk complexes.⁶¹

3.3 Dynamics

3.3.1 Axial Motion of Discs in Columnar Liquid Crystals

A unique strength of solid state NMR is its ability to probe molecular dynamics over many orders of magnitude with site selectivity and specific geometric sensitivity.^{19,62} High resolution DQ MAS of dipolar coupled spins has further broadened our tools in this area. This is illustrated by a few examples. Consider as a particularly simple case the rotation of the discs around the column axis in discotic liquid crystals.⁶³

Figure 9 (a) Solid state packing of a molecular tweezer. (b) ^1H DQ MAS NMR spectrum at 700 MHz, and (c) ^1H - ^{13}C HSQS MAS NMR correlation spectrum, for details see Ref.⁵⁶

In the past, studying this motional process required ^2H NMR of selectively labeled systems, which was indeed done for HBC.⁶⁴ The effort seemed justified in view of the favorable properties of these systems, i.e., extremely stable mesophase and record charge carrier mobility along the column axis.⁶⁵ This tedious approach can now be circumvented. Figure 12 presents ^1H DQ MAS spinning sidebands of HBC- C_{12} , containing C_{12} alkyl chains, in (a) the crystalline and (b) the LC phases.¹⁶ The aromatic protons are grouped as well separated pairs and, thus, an analysis within the spin-pair approximation is appropriate. As is evident from the insets on the right of Figure 12 the DQ-spinning sideband patterns are very sensitive to the strength of the dipolar coupling, which can be determined with high accuracy to yield values of (15 ± 0.9) kHz and (6 ± 0.5) kHz in the solid and the LC phase, respectively. The

reduction factor due the axial motion of the discs is thus 0.4 corresponding to an order parameter of 0.8, remembering that for a completely regular column the H-H vectors would be at right angles to the column axis and the reduction factor would be 0.5.¹⁹ The reduced order parameter indicates additional out-of-plane motion in addition to the axial rotation.

The limited order of these systems also shows up in the X-ray diffraction pattern displayed in Figure 13(a). The order can be increased by inserting phenylene units between the core and the alkyl chains (HBC-Ph C_{12}),⁶⁶ as is evident from the sharper X-ray reflections in Figure 13(b). In ^1H NMR, however, we cannot resolve the core and the exophenyl moieties. This can be achieved by heteronuclear ^1H - ^{13}C DQ NMR applying REPT-HMQC techniques.³⁷ Indeed, analysis of the sideband patterns for the C-H groups (Figure 13, lower part) yields core

Figure 10 (a) ^1H DQ MAS NMR spectrum (500 MHz) of an all silica ZSM zeolite. (b) Sideband pattern for the hydrogen bonded protons, for details see Ref.⁵⁷ (Reproduced by permission of American Chemical Society)

order parameters of 0.78 ± 0.09 and 0.93 ± 0.09 for HBC- C_{12} and HBC- PhC_{12} , respectively, indicating less out-of-plane mesogen mobility in the latter. The ease with which this information is obtained with 10 mg of as-synthesized samples made it possible to report such findings together with the synthesis of these new materials.⁶⁶

3.3.2 Slow Motions from Double-Quantum Exchange NMR

Multidimensional exchange NMR spectroscopy provides unique information about the time scale as well as the geometry of slow molecular motions,¹⁹ latest developments are described by Schmidt-Rohr (see **Centerband-Only Detection of Exchange (CODEX): Efficient NMR Analysis of Slow Motions in Solids**).⁶⁷ Extending DQ NMR spectroscopy into that area, therefore, represented a special challenge. Recently, such a homonuclear DQ-DQ exchange experiment has been designed⁶⁸ by combining two DQ experiments as depicted in Figure 14(a). The dipole-dipole coupling between two distinct spins is used to generate a DQ coherence, and the orientation dependent coupling is measured by means of the DQ-MAS sideband pattern before and after a mixing time. In a

reduced three-dimensional experiment, the two DQ-sideband patterns are correlated, resulting in a DQ-DQ sideband pattern which is sensitive to the reorientation angle. By referencing the DQ-DQ time signal, the information content of the pattern is divided into the sidebands and the centreband, with the former reflecting only the moieties which have undergone a reorientation changing the dipole-dipole coupling, and the latter predominantly containing contributions from moieties which retained their dipole-dipole coupling because they remained in, or returned to, their initial position. Hence a single sideband pattern provides access to the reorientation angle and the relative number of sites characteristic of the motional process. As a first example, Figure 14(b) displays calculated (black) and experimental (gray) ^{13}C - ^{13}C DQ MAS sideband patterns for the crystalline phase of doubly labeled poly(ethylene). The exchange spectra reflect the 180° flip motion due to the slow α -process of this material, yielding a C-C reorientation angle of $70 \pm 5^\circ$ in accord with 2D dipolar exchange NMR experiments on the same sample under static conditions.⁶⁹ One of the advantages of the MAS technique is its ability to probe the chain motion also in the non-crystalline regions, which is particularly important in view of the reviewed interest in the crystallization process of semicrystalline polymers⁷⁰ and the relation of the α -process to ultradrawability of such polymers.⁷¹

3.3.3 Chain Order and Translational Motion in Polymer Melts

High resolution DQ MAS NMR also offers new possibilities to probe dynamic processes involving considerably longer length scales. Figure 15 displays the ^1H DQ MAS NMR spectrum of 1.4 poly(butadiene) (PB) in the melt. The rapid segmental motion largely averages intra- and intermolecular dipole-dipole couplings, such that narrow lines result. Despite of that, strong auto- and cross-DQ peaks are observed, from which residual dipole-dipole couplings between the different protons can be determined.¹⁷ They result from the fact that the chain motion in an entangled melt is not completely isotropic on intermediate length- and timescales. Numerous ways have been designed to probe the resulting dynamic order parameters by NMR.⁷² ^1H DQ MAS NMR is the only way which can clearly distinguish *intra*- and *intergroup* couplings, and therefore determine order parameters for vectors directed *along* the chain, which were found to be considerably higher than anticipated.¹⁷

In order to quantify our findings, the measured order parameters are analyzed in terms of the celebrated reptation model of chain motion, formulated by De Gennes⁷³ and Doi and Edwards.⁷⁴ As depicted in Figure 16(a) the reptation model considers single chains subject to spatial restrictions due to entanglements, which are considered to act effectively like a tube through which the selected chain reptates. Four separate length- and timescales are distinguished (Figure 16(a)). In the different regimes different scaling laws for the mean-square displacement of chain segment due to *translational* motion are predicted, which also show up in the correlation function $C_R(t)$ probed by the residual dipole-dipole couplings, Figure 16(b). Here, the crossover from regime II ($t^{-1/4}$) to regime III ($t^{-1/2}$) is most indicative of reptation.^{17,75,76} This crossover is indeed observed in polymer melts as shown for

Figure 11 ^1H DQ MAS NMR spectra (700 MHz) for a PSS/PDADMAC polyelectrolyte complex (a) and polyelectrolyte multilayer on a silica surface (b). For details see Ref.¹⁸

Figure 12 ^1H - ^1H DQ spinning sideband patterns of HBC- C_{12} in the solid state (a) and in the columnar liquid crystalline phase (b), where the discs rotate around the column axis as indicated. For details see Ref.¹⁶ (Reproduced by permission of American Chemical Society)

PB in Figure 16(c),^{17,76} which forces us to conclude that the characteristic length scale for the residual dipole-dipole couplings is indeed the entanglement length, i.e., nanometers.^{73,74} Thus, DQ NMR emerges as a simple alternative to neutron

scattering for probing the chain organization of polymers.⁷⁷ Further insight was provided through a recent study,⁷⁶ where the effect of restricting the chain motion by anchoring one or both chain ends in polystyrene (PS)-PB blockcopolymers

Figure 13 Comparison of powder wide angle X-ray patterns (a) and heteronuclear ^1H - ^{13}C DQ spinning sideband patterns (b) of HBC-C₁₂ (a) and HBC-PhC₁₂ (b). For details see Ref.⁶⁶

was investigated (Figure 16(c)). Not only did the chain motion slow down, the order parameters were found to increase drastically in these systems, where the polymer melt is confined to lamellae of a few tens of nm. These observations lead us to conclude that amorphous polymers are, in fact, structured in terms of nanodomains,⁷⁶ which is also consistent with new views of polymer crystallization from the melt.⁷⁰

4 CONCLUSIONS AND OUTLOOK

Only a few years after the first DQ MAS spectra of strongly dipolar coupled solids have been recorded¹¹ this type of spectroscopy has emerged as a powerful tool for structural and dynamical elucidation of complex systems. This overview has focused on applications in soft matter research, i.e., on supramolecular organic systems, where spectra are recorded on small amounts (10–15 mg) of as-synthesized samples and the results are obtained overnight; but the methodology can be applied in general. For instance, high resolution DQ MAS NMR spectroscopy of isotopically labeled systems of biological interest yields torsional angles in peptides^{78,79}

and thus important information about the chain conformation. The sensitivity of ^1H chemical shifts to ring current in aromatic systems has been exploited in determining the packing of porphyrines.³⁴ The full information about distances and the relative orientation of specific moieties is available from DQ-NMR spectroscopy on static samples of specifically labeled materials⁸⁰ and has provided important information about the chain conformation and packing of synthetic macromolecules.⁸¹ Last, but not least, DQ MAS NMR spectroscopy has provided hitherto inaccessible information about the connectivity of building blocks and medium range order of inorganic glasses.^{82,83}

The development of the technique is far from complete. Major advances are expected in the years to come. For instance, selection of coherence pathways by pulsed field gradients, well-established in high-resolution NMR in liquids, has recently been demonstrated in rotating solids.^{84,85} Likewise, inverse detection and heteronuclear editing has been realized in MAS NMR in both, synthetic polymers and biopolymers.^{86,87} Indeed, an increase of the signal to noise ratio by a factor of 10 has been achieved for ^{15}N by such an approach.⁴⁹ Thus solid state NMR is envisaged to become as valuable a tool for the supramolecular chemist as solution state NMR is for the synthetic chemist today.

Biographical Sketch

Hans Wolfgang Spiess, b 1942. Ph.D., 1968, Physical Chemistry, University of Frankfurt, Germany. Research associate, Florida State University, 1968–1970; Max-Planck Institute, Heidelberg with K. H. Hausser, 1970–1975; University of Mainz, 1975–1978. Professor at University of Mainz, 1978–1980. University of Munster, 1981–1982. University of Bayreuth, 1983–1984. Director, Max-Planck-Institut for Polymer Research, Mainz since 1984. Approx. 350 publications and a monograph on multidimensional solid-state NMR and polymers. Current research interests: solid state NMR and its applications in polymer science and supramolecular systems.

Dynamic Angle Spinning

Philip J. Grandinetti

The Ohio State University, Columbus, OH, USA
